

Fig. 46.27 Postero-anterior diagnostic triangles: (1) the maxillary triangle, (2) the mandibular triangle, and (3) the chin triangle.

- tically, surgically, or later by placement of an implant.
2. Occlusal curves in the upper and/or lower dental arches can be more accurately assessed on dental models. Orthodontic leveling of the curve of Spee in the lower arch will require 1mm of antero-posterior space for every 1mm of leveling of the curve. It should be kept in mind that when leveling occlusal curves is done by intruding or extruding teeth more than 2mm the result may not be stable. Careful assessment of the occlusal curves is significant to decide whether extractions are required and whether the curve should be leveled orthodontically or surgically (Fig. 46.28).
 3. Tooth sizes and arch length. Crowding or spacing can be assessed on the models by measuring the arch length and comparing it to the total amount of tooth width.
 4. Tooth mass discrepancies. Tooth mass discrepancies are not uncommon in patients with dentofacial deformities and are often the result of congenitally absent or small upper lateral incisors. In these cases it is problematic to establish an occlusion that will meet all the objectives of an ideal class I dental relationship. Bolton's analysis is a method to correlate the sizes of the six upper incisor teeth with the sizes of the lower six incisor teeth. When the combined width of the lower incisors is divided by the combined width of the upper incisors and

multiplied by 100 it should yield a value of 77.2%. When the combined width of the upper incisors is divided by the lower incisor width it should yield a value of 1.3 and is called the Bolton's intermaxillary index. When the Bolton's index deviates from the normal ratio it may be necessary to either reduce the width of the lower incisors or to leave spaces distal to the upper lateral incisors. The spaces can be closed by means of restorative dentistry. In severe cases, with a discrepancy of more than 5mm, extraction of a lower incisor may be considered. Tooth size discrepancies may also occur between the posterior teeth. For Bolton's tooth ratio analysis the sum of the widths of the 12 mandibular teeth is divided by the sum of the 12 maxillary teeth and multiplied by 100. A value of 91.3% will result in optimal posterior occlusion and incisor overjet and overbite. If the value is greater than 91.3%, the problem is usually as a result of excessive mandibular tooth mass.

5. Tooth-bone relationship. The angulation and position of the upper and lower incisors in relation to the bony base should be assessed. This will determine whether tooth extractions are indicated. In cases where the maxillary arch is narrow and may need expansion, the relationship of the molar teeth and the bone will assist in the decision to either expand the arch orthodontically or surgically.
6. Dental arch form and symmetry. A problem with symmetry usually occurs when a tooth is missing on one side and often results in dental midline asymmetry. Dental arch form is important for arch compatibility and will either require special orthodontic mechanics, asymmetric tooth extraction, or additional surgical procedures.
7. Buccal tooth tipping (curve of Wilson). The curve of Wilson is often accentuated in class III cases with the upper molars buccally inclined and the lower molars lingually inclined. It is not possible to achieve an acceptable occlusion during surgery with the occlusal surfaces of the posterior teeth tipped buccally. Buccal tipping in cases with maxillary transverse deficiency increases the amount of skeletal expansion (Fig. 46.29).

Fig. 46.28 (a) An accentuated curve of Spee is present and the lower incisor teeth are upright. Leveling the occlusal curve will increase the arch length and procline the lower incisors. In this case the bony base will accommodate all the teeth. (b) The lower incisors are proclined in combination with an accentuated curve of Spee. Orthodontic leveling of the arch will procline the incisors excessively. Extractions are indicated to accommodate all the teeth.

Orthodontic principles in orthognathic surgery

Most people with irregular teeth and jaw deformities usually seek treatment from an orthodontist and it is the orthodontist's task to introduce the patient to the treatment principles and the need for surgery as part of the treatment plan. The final pretreatment consultation takes place only after a systematic patient evaluation has been conducted and the orthodontist and surgeon have agreed on a final treatment plan. The clinician should be confident, explanations should be kept simple, and the patient's radiographs and dental casts should be used to demonstrate the problems.

Fig. 46.29 (a) The molar teeth are placed in the center of the bone with normal angulation. Surgical expansion requiring 5 mm increase of the arch width will require 5 mm bony expansion. (b) An accentuated curve of Wilson is present and the molars are tipped buccally. In this case a 5 mm increase of dental arch width will require a 10.5 mm bony expansion.

Treated cases with similar problems can be used to demonstrate the treatment objectives and simple diagrams of the intended surgical procedure should be used. Pictures of actual surgery should be avoided. More detailed information and explanations regarding the surgery should be left to the surgeon.

It is mandatory that the patient (and family) be well informed because, as a general rule, a well informed patient usually follows instructions and is easy to treat. The authors explain to patients that a typical treatment profile consists of six stages:

- *First stage:* placement of orthodontic bands. Before placement of the bands all necessary extractions including third molars should be done.
- *Second stage:* presurgical orthodontic treatment. The teeth will now be aligned according to the treatment plan. Once the orthodontist is happy that the presurgical orthodontic treatment objectives have been achieved the objectives are checked by means of a cephalometric radiograph and cast models. The patient is then referred back to the surgeon. This treatment stage usually lasts an average of 9–18 months.
- *Third stage:* surgical stage. The surgical repositioning of the jaw(s) is now performed. After a short healing time of 2–3 weeks the patient returns to the orthodontist. Although the orthodontist will not actively start with orthodontic tooth movement it is important to: (1) evaluate the postoperative

occlusion and communicate any concerns to the surgeon; (2) consider postoperative orthodontic control of the surgical movements.

- *Fourth stage:* postoperative orthodontic treatment to perfect the bite. This stage of the treatment should take approximately 3–6 months. If this phase takes longer than 6 months the clinician should re-evaluate the treatment plan and achievement to date and assess problems. Patients, in general, become very impatient and their enthusiasm for further orthodontic treatment dwindles following surgery. It is for this reason that the authors recommend that, whenever possible, most orthodontic treatment should be performed before surgery.
- *Fifth stage:* removal of orthodontic bands.
- *Sixth stage:* retention stage (6–12 months). Following orthodontic tooth movement and surgical repositioning of the jaws the teeth need to be stabilized in their new positions for a time. The orthodontist manufactures and fits a retention appliance, which must be worn by the patient as instructed by the orthodontist. The patient should be seen by the clinicians for at least 1 year following band removal to monitor dental and skeletal stability and any unfavorable changes should be recorded.

It is important that the clinicians communicate with each other following each stage, often with a short note confirming the progress of the treatment. Any

orthodontic problems that have occurred that may influence the presurgical preparation, or any orthodontic corrections which the orthodontist may prefer to complete after surgery, should be communicated to the surgeon. Whether the surgical procedure should occur early or late in the orthodontic phase depends on the patient, the patient's growth status, the deformity, and the treatment team. Surgery can be performed either after most of the orthodontic tooth movement has been completed or may be performed early in the orthodontic phase. Completing nearly all the orthodontics before surgery has certain advantages:

- surgical repositioning of the jaws can be done more accurately once the teeth are well aligned;
- the risk of not meeting the treatment goals during postsurgical orthodontics is reduced;
- a better occlusion at the time of surgery enhances stability;
- a certain amount of orthodontic tooth movement has to be done before surgery anyway;
- after surgery and improved esthetics the patient's enthusiasm and cooperation dwindle.

Performing surgery early in the orthodontic phase also has certain advantages:

- orthodontic tooth movement after surgery is probably more rapid as a result of accelerated bone metabolism and increased rate of bone remodeling;
- early esthetic improvement for the patient;
- treatment time may be increased in an attempt to do most orthodontic alignment before surgery.

Postsurgical orthodontics

After the surgery, it is mandatory that the surgeon report to the orthodontist that the surgical objectives have been achieved according to the treatment plan or whether any surgical problems have been encountered which may have an influence on the postoperative orthodontics and/or the final result. The surgeon should not expect the orthodontist to correct surgical problems. Any postoperative problems such as incorrectly positioned condyles, fixation failure, etc. should be promptly recognized and corrected by the surgeon before turning care over to the orthodontist. An advantage of using internal rigid fixation is that intermaxillary fixation is not necessary and it allows early orthodontic intervention following surgery. Earlier physiotherapeutic rehabilitation of range of motion is also possible.

Postsurgical orthodontics can start 3–4 weeks after surgery. The teeth can be moved rapidly in the first 10 weeks following surgery and the orthodontist should see the patient every 1–2 weeks for adjustments during the first 2–3 months so that changes can be monitored closely. The same principles regarding

retention apply for orthognathic patients as for routine orthodontic patients.

Orthodontics without prior surgical consideration

Occasionally the orthodontist may start orthodontic treatment, not considering the need for surgery. Once the indication for surgical correction is realized by the orthodontist, the patient should be informed and the need for surgery explained. In cases where this situation does arise the orthodontist and surgeon should compare the pretreatment records with the current situation and assess the stability of the orthodontic mechanics. If there are any concerns regarding the stability of the dental alignment within the arches as a result of unfavorable tooth movement, the teeth should be allowed to settle for 4–6 months. The arch wires can be sectioned and the teeth be allowed to relapse (vertically and horizontally) while maintaining correction of any rotations. Unfavorable tooth movements with questionable stability may include dental expansion beyond the bony base, proclination of incisors out of the central trough of bone and intrusion or extrusion of teeth to close an anterior open bite.

After a settling period the patient should be re-evaluated and a new diagnosis and treatment plan formulated. Unfortunately some compensatory orthodontic treatment cannot be reversed, e.g. tooth extractions that might not have been done in a combined surgical–orthodontic treatment plan. Correction may now require surgical procedures that may not have been contemplated if surgery was considered in the first place.

Esthetic objectives and surgical solutions

The esthetic goals of each case will dictate the choice of the surgical procedure and are influenced by the patient's main complaint and the facial esthetic examination and treatment goals. Surgical treatment for the correction of dentofacial deformities is based on five basic treatment scenarios:

1. Single jaw surgery – lower jaw.
2. Single jaw surgery – upper jaw.
3. Double jaw surgery – upper and lower jaw.
4. Double jaw surgery – rotation of the maxillomandibular complex.
5. Chin surgery.

The esthetic goals are planned by the development of a cephalometric visual treatment objective. First a soft tissue esthetic objective is developed followed by an orthodontic treatment objective to ascertain where the teeth should be positioned to facilitate the planned surgical procedure and, in turn, the soft tissue goals.

Various possibilities should be considered when integrating the esthetic goals, the orthodontic treatment objectives, and the indicated surgical solutions with the development of the visual treatment objectives. Consider a case with mandibular antero-posterior deficiency requiring an increase in mandibular prominence. Several surgical solutions may be considered:

1. Surgical advancement of the mandible.
2. Surgical advancement of the mandible and the chin.
3. Surgical advancement of the chin.

The choice of the surgical procedure will be influenced by several factors:

1. The dental occlusion.
2. The mandibular skeletal base position.
3. The shape of the chin.

Each scenario will also have certain orthodontic solutions. The preoperative positioning of the teeth will dictate the nature and extent of the surgical procedure and will also influence the final esthetic result. The orthodontic treatment objectives should be coordinated with the esthetic requirement and this will influence the extraction pattern, the amount of dental decompensation, the required occlusal curve leveling, etc. It should be kept in mind that the orthodontic treatment objectives for surgical–orthodontic treatment often differ and, in many cases, are opposite to those of non-surgical cases.

Treatment principles for various surgical treatment scenarios

Single jaw surgery: mandibular repositioning

The dentition, especially the incisors of the unoperated jaw, in this case the maxilla, will determine the

new antero-posterior, transverse, and vertical position of the mandible (Fig. 46.30). The position and shape of the chin may, however, be changed by means of a genioplasty. Chin surgery is not a substitute for mandibular surgery and genioplasty should be performed to improve the shape of the chin (vertically, transversely, and antero-posteriorly) and not primarily to improve the chin projection (to position pogonion correctly). In cases requiring only mandibular surgery, the following aspects should be considered by the orthodontist and the surgeon:

Orthodontic considerations

1. Maxillary incisor position and angulation. Cephalometric guidelines should be followed to position the incisor teeth; however, in mandibular-deficient cases the upper incisors should not be retracted excessively. Excessive retraction of the upper incisors will reduce upper lip support and limit the amount of mandibular advancement in class II cases, while this will increase the amount mandibular setback with negative esthetic effects in class III cases.
2. Mandibular incisor. In mandibular-deficient cases there is often dental crowding present requiring tooth extractions. There are three extraction patterns that may be implemented: (1) where crowding in the anterior mandibular arch is present, the lower first bicuspid should be extracted – this will allow for arch alignment as well as sufficient lower incisor retraction when required; (2) the second bicuspid are usually removed in cases where there is crowding in the mid-arch – extraction of bicuspid in the lower arch only will lead to a class III molar and class I canine relationship. The lower incisors are often compensated (retroclined in class III cases and proclined in class II cases); (3) although seldom necessary, a lower incisor can be extracted. Extraction of a lower incisor may shorten the orthodontic treatment time, however

Fig. 46.30 The patient in (a) requires mandibular advancement. The mandible has been advanced (b) and the maxilla (the unoperated jaw) dictated the final antero-posterior (1) and vertical (2) position of the mandible.

will lead to a tooth size discrepancy. The amount of decompensation is primarily influenced by the bone thickness in the symphysis area and the amount of jaw repositioning that is required to achieve the best esthetic result, postoperative stability, and periodontal situation.

3. Dental midline. Ensure that the dental midline in the upper arch (unoperated jaw) is corrected orthodontically. In cases where the mandible is asymmetric the orthodontist should attempt to position the lower dental midline in the center of the chin so that facial asymmetry will be corrected by the mandibular surgery. Final mandibular asymmetry can, however, be corrected by genioplasty.
4. Maxillary arch form and rotation. The upper dental arch forms the template for the surgeon to position the mandible. Although the mandibular arch width can be surgically altered it is not done routinely. The orthodontist should ensure that the maxillary arch width, especially the intercanine width, will accommodate the lower arch after

repositioning. In class III cases there is often a tendency for the maxillary posterior teeth to be buccally inclined while the lower posterior teeth tend to be lingually inclined. This should preferably be corrected orthodontically before surgery.

5. Dental arch compatibility. One of the best tooth retainers is a good occlusion. It is therefore preferable that the teeth fit into a reasonable occlusion at the time of surgery. The orthodontist can monitor the arch compatibility during the presurgical treatment phase by means of check dental casts.
6. Leveling the occlusal curves. The occlusal curves in the maxillary arch should be leveled before surgery, however this is not always the case for the lower dental arch. In class II low mandibular plane angle cases with short lower facial heights, the curve of Spee should not be leveled before surgery. Surgical advancement of the mandible would result in an increase in lower facial height (Fig. 46.31). In cases with normal or increased lower facial height, the occlusal curve in the mandible should be leveled before mandibular advancement.

Fig. 46.31 The accentuated curve of Spee is not leveled before surgery. Advancement of the mandible will result in a three-point contact occlusion and bilateral open bites. The lower incisors will advance more than the chin (Pog) (1). The advancement and rotation of the mandible will also result in an increase in mandibular height (2).

Surgical considerations

1. The maxillary dental arch will dictate the amount of surgical advancement or setback of the mandible. The transverse mandibular position will be determined by the upper posterior teeth, while the antero-posterior position, midline, and height of the lower incisors will be guided by the upper incisors.
2. The chin position and shape can be altered by genioplasty

Single jaw surgery: maxillary surgery

As in the first treatment scenario, the final position of the jaw to be operated on (maxilla) will be determined by the unoperated jaw (mandible) (Fig. 46.32). In this

Fig. 46.32 The mandible (the unoperated jaw) will determine the final antero-posterior position of the maxilla. However any vertical correction of the maxillary height will result in upward and forward rotation following superior repositioning or downward and backward rotation of the mandible following down graft (2).

scenario, however, the surgeon may alter the height of the maxilla by inferior or superior repositioning. When the maxillary height is increased by downgrafting or decreased by superior repositioning, the mandible will autorotate around a point at the condyle. This clockwise or counterclockwise rotation will alter the antero-posterior position of the lower incisors which will demand consideration. This treatment scenario will require additional surgical and orthodontic considerations.

Orthodontic considerations

1. Maxillary incisor position and angulation. Dental crowding is often present in class III cases as a result of maxillary antero-posterior deficiency, and extractions may be required in the upper arch to align the teeth. Three extraction patterns may be implemented: (a) crowding in the maxillary arch and no crowding in the lower arch – extract the first bicuspid; (b) crowding in the posterior maxillary arch – extract the second bicuspid; (c) crowding in both arches – extract the first upper bicuspid and the second lower bicuspid. These extraction patterns will obviously be influenced by other factors, such as tooth prognosis, the area of crowding, and tooth angulation or compensation. Orthodontic alignment and correction of incisor angulation should be done before surgery.
2. Lower incisor position. The lower incisor position is determined by factors described above, however in this scenario the final antero-posterior position of the lower incisors will change following vertical change and mandibular autorotation and should be planned according to the surgical visual treatment objective. In high occlusal plane angle cases the antero-posterior change is more than in low occlusal plane cases.
3. Occlusal curves. The curve of Spee should be leveled, as in this scenario the lower arch acts as the template. Occlusal curves in the upper arch should also be leveled before surgery, however there is often a natural step in the maxillary arch especially in open bite cases. In these cases as well as cases requiring surgical expansion, the arch should be aligned in segments and the roots of the teeth adjacent to the intended interdental osteotomies must be deviated.
4. Dental arch compatibility. The arch form of the segments should be coordinated with the lower arch form.
5. Dental midlines. The dental midline of the lower arch should be coordinated with the facial midline. The orthodontist should not waste treatment time by correcting the upper dental midline as this can be done surgically.
6. Preparation for segmental surgery. Surgical alteration of the maxillary arch or correction of occlusal curves (open bite cases) may be indicated. The orthodontist should deviate the roots of the teeth

in the intended interdental osteotomy areas before surgery. Root deviation should be more prominent when interdental closure of spaces is planned than when only differential vertical repositioning of the segments is required.

Surgical considerations

1. Antero-posterior positioning of maxilla. The final horizontal position of the maxilla will be determined by the antero-posterior position of the lower incisor. However, with any vertical change in the position of the maxilla, the mandible will autorotate thereby changing the horizontal position of the lower incisor. With superior repositioning of the maxilla the lower incisor will rotate anteriorly, while with inferior repositioning of the maxilla the lower incisor will rotate posteriorly. With high mandibular plane angle cases the antero-posterior changes following autorotation are more than with low angle cases. These geographic changes should be considered in relation to the esthetic consequences (Fig. 46.33).
2. Vertical positioning of the maxilla. Surgical repositioning of the maxillary incisor in its most favorable antero-posterior and vertical position is one of the most important keys to orthognathic treatment.
3. Transverse corrections. Maxillary surgery also allows the surgeon to alter the transverse dimension of the upper arch. By performing segmental surgery the surgeon can either expand or narrow the maxillary dental arch to fit the mandibular arch. The interdental osteotomies are placed either between the upper lateral incisor and canine tooth or between the canine and bicuspid tooth. The authors prefer to place the interdental osteotomies between the lateral incisor and the canine tooth. The alveolar bone is thin in this area, surgical sight is easily accessible, the surgeon can control the

Fig. 46.33 The height of the maxilla (1) may be changed, which will have an effect on the final antero-posterior position of the lower incisor as a result of the rotation of the mandible (2).

Fig. 46.34 (a) The interstitial osteotomies are placed between the canine and first bicuspid teeth. (b) The interstitial osteotomies are placed between the lateral incisor and canine teeth. In both cases the interstitial osteotomies are combined with palatal osteotomies.

Fig. 46.35 (a) Surgical closure of interdental spaces will require adequate deviation of the roots of the teeth adjacent to the interdental osteotomies. (b) To ensure integrity of the periodontium, interdental spaces should never be completely closed, and a small amount of bone should always be left intact at the alveolar crest.

intercanine width, and, by deviating the roots, the canine tooth is orthodontically close to its final position and need not be moved following surgery (Fig. 46.34).

4. Occlusal curves. By performing segmental surgery the surgeon can level occlusal curves that may exist in the upper arch. Differential vertical repositioning of the anterior and posterior segments will allow the mandible to autorotate and, for example, close an anterior open bite.
5. Closure of interdental spaces. Segmental surgery also allows the surgeon to close interdental spaces. Orthodontic deviation of the roots of the teeth adjacent to interdental osteotomy areas must be adequate to prevent damage to the tooth roots during surgery (Fig. 46.35a). An area of alveolar bone should always be maintained around the crest area to prevent periodontal problems (Fig. 46.35b).

Double jaw surgery: repositioning the maxilla and the mandible

When the treatment plan demands surgery to both jaws, the surgery to either jaw can be performed first. The authors prefer to perform upper jaw surgery first. Once the upper jaw procedure has been completed the final position of the mandible will be determined by the maxilla and the principles of single jaw surgery then apply.

Orthodontic considerations

1. Tooth extractions. The extraction of teeth when indicated will be influenced by the following: crowding (anterior or posterior), the required incisor discrepancy (overjet or crossbite) to facilitate the ideal jaw movements, dental stability, and leveling of occlusal curves.
2. Correction of transverse occlusal cants. If an occlusal cant exists in a patient with facial asymmetry, surgical correction of the cant will often play an important role in the correction. The cant should therefore not be corrected orthodontically.
3. Incisor position. Ensuring proper incisor angulation as well as establishing the planned discrepancy between the upper and lower incisor teeth will facilitate the required jaw movement.
4. Dental arch form and interarch compatibility will enhance good intercuspation during surgery which will improve postoperative stability.
5. Dental midlines. The orthodontist should not waste treatment time by correcting dental midlines. Dental midlines can be corrected during surgery.
6. Transverse problems. Transverse discrepancies involving dental tipping should be corrected orthodontically. The teeth must not be moved beyond their bony base, however, as this may result in relapse (Fig. 46.29). Although it is possible to alter the width of the mandibular arch surgically

it is seldom indicated. It is generally necessary to establish a good lower arch form before surgery. Transverse skeletal discrepancies can be corrected by either surgically assisted palatal expansion or segmental surgery. Buccal tipping of the posterior teeth will accentuate the curve of Wilson. Before surgical expansion the orthodontist should ensure that the posterior teeth are upright (level the curve of Wilson) and in the central trough of bone because buccally tipped molars will increase the amount of surgical palatal expansion (Fig. 46.29).

Surgical considerations

The “responsibility” and considerations of the surgeon increase when planning and performing two jaw surgeries. However, once the first jaw is positioned, it is like a single jaw surgery case, with the jaw positioned first determining the position of the second jaw. It is therefore mandatory that surgery be performed accurately. With the advent of rigid fixation, either jaw can be operated on first, however the authors prefer to perform surgery to the upper jaw first. The following are important factors to consider by the surgeon:

1. Vertical position of the anterior maxilla. The position is determined by the upper incisor upper lip relationship.
2. Antero-posterior position of the mandible. The antero-posterior position of the mandible will change following alteration of the height of the maxilla. A decrease in maxillary height (maxillary superior repositioning) will cause the mandible to rotate anteriorly (clockwise around the condyle). An increase in the maxillary height (maxillary downgraft) will cause the mandible to rotate posteriorly (Fig. 46.33).
3. Vertical position of the posterior maxilla. In conventional treatment planning, when maxillomandibular complex rotation is not contemplated, the vertical position of the posterior maxillary teeth is dictated by the mandibular molars. Any vertical change in the maxilla (superior or inferior) will result in autorotation of the mandible (around a point at the condyle) altering the height of the mandibular molars. Correction of anterior open bite often requires differential superior repositioning of the anterior and posterior maxilla.
4. The height of the right and left sides of the maxilla. There is often a transverse cant of the occlusal plane present in facial asymmetry cases. Surgical correction of the cant usually assists with overall correction of the facial asymmetry and the final occlusal plane should be parallel to the interpupillary line, given that the interpupillary line is horizontally correct. Correction of the height of the left and right sides of the maxilla will have an influence on the vertical position of the maxillary incisor, the transverse position of the upper dental

midline, as well as the symmetry of the chin, which should be kept in mind during planning and execution of surgery.

5. Antero-posterior position of the maxilla. Esthetic considerations, such as paranasal form, upper lip support, nasolabial angle, and facial contour, will determine the final antero-posterior position of the maxilla.
6. Maxillary arch rotations. The left and right sides of the maxilla should be advanced equally to ensure facial symmetry.
7. Dental midlines. When both jaws are surgically repositioned the surgeon is responsible for positioning the dental midlines in the middle of the face and the orthodontist should not waste treatment time by correcting dental midlines. It is extremely disappointing to realize that the dental midlines were eccentrically positioned during surgery – the day following surgery.
8. Transverse width of the dental arches. The width of the maxillary dental arch is determined by the width of the mandibular arch unless surgical change of the lower arch is contemplated. A narrow upper arch due to dental tipping should be corrected orthodontically. Skeletal transverse deficiency in growing individuals can be corrected by orthodontic rapid palatal expansion, while in adults the transverse dimension of the maxilla can be increased by surgically assisted expansion or surgical segmental expansion. Care should be taken not to damage the tooth roots of the teeth adjacent to the interdental osteotomies and to preserve the integrity of the periodontium by leaving a small amount of bone at the alveolar crest (Fig. 46.35).

Double jaw surgery: rotation of the maxillomandibular complex

A satisfactory functional, stable, and esthetic result may be achieved by correcting dentofacial deformities according to conventional orthognathic treatment design. Adhering to conventional treatment designs may, however, hamper achievement of optimal esthetic results, especially in severe high or low occlusal plane angle cases. Rotation of the maxillomandibular complex and the consequent alteration of the occlusal plane is a surgical design that will allow the surgeon to achieve certain esthetic results that cannot be achieved by conventional treatment methods.¹⁶ In this treatment scenario the final occlusal plane angle will not be determined by the occlusal plane of the mandible.¹⁷

Orthodontic considerations

The orthodontic treatment considerations in this scenario are the same as discussed for two jaw surgery. Special attention should, however, be given to the angulation of the incisor teeth, because the incisor

angulation will also change as a consequence of the rotation of the maxillomandibular complex. The orthodontist may have to compensate for the change in angulation.

Surgical considerations

The surgeon has two more decisions to make in this scenario.

1. The direction of rotation of the maxillomandibular complex. In general patients with concave profiles will require clockwise rotation, while patients with convex profiles will require counterclockwise rotation of the maxillomandibular complex (Fig. 46.36). See Tables 46.11–46.14.
2. The point around which the maxillomandibular complex should be rotated. To simplify the planning and to allow visualization of the effects of the rotation, a triangle is constructed involving the anterior nasal spine (ANS), the posterior nasal spine (PNS), and pogonion (Pog). By changing the direction of rotation and varying the point of rotation on the triangle the esthetic possibilities can be investigated (Fig. 46.37). The actual rotation point

at the time of surgery will differ from the point on the treatment objective. It will be on the Le Fort I osteotomy line and should be determined by the surgical visual treatment objective.¹⁸ In general the following rules will apply:

- *The antero-posterior position of the chin (Pog).* The surgeon should first ensure that the shape and form of the chin are esthetically pleasing. This may require genioplasty and the position of pogonion should be evaluated once the chin shape is satisfactory. The higher and more anterior the rotation point the more pronounced the antero-posterior movement of the chin (Fig. 46.38).
- *Paranasal areas and ANS.* The lower the rotation point on the line between the ANS and Pog, the more pronounced the antero-posterior movement of the ANS (Fig. 46.39).
- *Vertical changes.* Any rotation point on the line between the PNS and the ANS will also have vertical implications (Fig. 46.40).

Counterclockwise rotation is very seldom performed using Pog as the rotation point as this design will result in excessive setback of the maxilla. Maxillary setback, in most cases, would result

Table 46.11 Counterclockwise rotation of the maxillomandibular complex – hard tissue changes.

	Rotation point and effects			
	ANS	Incisor tip	Zygomatic buttress	PNS
OP angle	Decrease	Decrease +	Decrease +	Decrease ++

**Fig. 46.37** The concept of rotating the maxillomandibular complex can be simplified by constructing a triangle including PNS, ANS, and Pog.

in poor esthetics. Clockwise rotation, however, would enhance maxillary advancement and, in many cases, is esthetically advantageous. Tables 46.11–46.14 summarize the effects, at seven sites, of rotation of the MMC at the four most commonly used rotation points.

Chin surgery

The prime goal of genioplasty is to improve the shape of the chin. Surgical advancement of the chin should not be performed for individuals requiring mandibular advancement. This may achieve the correct chin projection (pogonion in correct antero-posterior

Fig. 46.38 (a) Counterclockwise rotation of the maxillomandibular complex around ANS. The posterior maxilla is repositioned inferiorly, and the incisor teeth and chin are advanced. The expected hard and soft tissue changes are summarized in Tables 46.11 and 46.12. (b) Clockwise rotation of the maxillomandibular complex around ANS. The posterior maxilla is repositioned superiorly, and the incisor teeth and chin move posteriorly. The hard and soft tissue changes are summarized in Tables 46.13 and 46.14. (c) Clockwise rotation of the maxillomandibular complex around the incisor tip. The posterior maxilla is superiorly repositioned, ANS is advanced and the chin moved posteriorly. The expected hard and soft tissue changes are summarized in Tables 46.13 and 46.14. (d) Counterclockwise rotation of the maxillomandibular complex around the incisor tip. The posterior maxilla is inferiorly repositioned, ANS is moved posteriorly and the chin advanced. The expected hard and soft tissue changes are summarized in Tables 46.11 and 46.12.

Fig. 46.39 Clockwise rotation of the maxillomandibular complex around Pog. ANS and the incisors are advanced. The expected hard and soft tissue changes are summarized in Tables 46.13 and 46.14.

position), however the balance and harmony of the chin will be compromised (Figs 46.41 and 46.42). In profile view the authors use seven criteria for the esthetic evaluation of the chin which also serve as a guide to surgical treatment planning (Fig. 46.43):

1. The height of the chin. The height of the chin should be equivalent to two thirds of the lower facial height (subnasale to stomion inferius (S^1): stomion inferius (S^1) to Me). The linear measurement should be 40 ± 2 mm for females and 44 ± 2 mm for males (1 in Fig. 46.43).
2. Vermillion exposure. The lower lip vermillion exposure should be approximately 25% more than the upper lip vermillion (2 in Fig. 46.43).
3. The labiomental fold. The contour of this fold should form a smooth curve connecting the lower lip with the chin. The depth of the fold should

Fig. 46.40 (a) Clockwise rotation of the maxillomandibular complex around the zygomatic buttress. ANS moves inferiorly and the incisors and Pog move posteriorly. The expected hard and soft tissue changes are summarized in Tables 46.13 and 46.14. (b) Counterclockwise rotation of the MMC around the zygomatic buttress. ANS, incisor tip and Pog move anteriorly and superiorly. The expected hard and soft tissue changes are summarized in Tables 46.11 and 46.12. (c) Clockwise rotation of the MMC around the PNS. The incisor tip and Pog move posteriorly and inferiorly. The expected hard and soft tissue changes are summarized in Tables 46.13 and 46.14. (d) Counterclockwise rotation of the MMC around the PNS. The incisor tip and Pog move anteriorly and superiorly. The expected hard and soft tissue changes are summarized in Tables 46.11 and 46.12.

Fig. 46.41 (a) The mandible is antero-posteriorly excessive, however the chin contour is esthetically pleasing. (b) Mandibular excess corrected by mandibular setback results in an esthetically pleasing profile. (c) Reduction genioplasty for the patient results in poor chin esthetics with obliteration of the labiomental fold.

Fig. 46.42 (a) The profile of a patient with mandibular antero-posterior deficiency but with esthetically pleasing chin contour. (b) Mandibular advancement results in a pleasing profile. (c) Advancement of the chin by means of a genioplasty deepens the labiomental fold and gives the chin a knobby appearance.

Fig. 46.43 The seven criteria used for the esthetic evaluation of the chin.

divide the lower lip chin into an upper third and lower two thirds. Individuals with mandibular deficiency often exhibit deep labiomental folds while mandibular excessive individuals will often exhibit flat folds (3 in Fig. 46.43).

4. Lower lip-chin-throat angle. This angle should measure $110 \pm 8^\circ$ and tends to be more acute in mandibular prognathic individuals and more obtuse in patients with mandibular deficiency (4 in Fig. 46.43).
5. Chin-throat length. The normal length is considered to be 42 ± 6 mm. Individuals with short chin-throat lengths would obviously benefit from chin advancement while those with prominent chin buttons and deep labiomental folds would benefit from a chin setback procedure (5 in Fig. 46.43).
6. Curvature of the chin. The profile of the chin should form a smooth S-shaped curve from lower lip superior to Me (6 in Fig. 46.43).
7. Lower lip position. The lower lip should be 2 ± 2 mm behind the E-line. The E-line is drawn from the nasal tip (Pn) to pogonion (Pog) (7 in Fig. 46.43).

Patients see themselves from the frontal view and evaluate their chin esthetics from their image in a mirror. Frontal evaluation of the face and chin is therefore as important as the profile assessment.

1. Facial and chin form. The general facial form, round, oval, square, or long, should correlate with the form of the chin. It is expected that females have smaller more rounded chins, while it is considered more attractive for males to have broad, square-shaped chins. The mandible should have a well defined smooth inferior border, from angle to symphysis, with a definite separation of the lower third of the face from the neck. An ill defined lower border of the mandible distracts from good chin-neck esthetics.
2. Transverse dimension. The width of the chin should be in balance with the bigonial and bizygomatic facial widths. Patients with leptoprosopic facial features often have a transversely deficient, "pointed" chin that seems separate from the mandible. Advancement of the chin by means of a sliding genioplasty may improve the profile, however this will accentuate the "pointiness" from the frontal view. For these patients an advancement of the chin should be combined with simultaneous transverse augmentation by means of a two-piece genioplasty (Fig. 46.13d). The esthetically pleasing chin should not have any parasymphyseal depression or "marionette grooves" which are often accentuated with age. An advancement genioplasty without lateral augmentation will deepen these grooves.
3. Chin asymmetry. There are three factors which should be considered when assessing the symmetry of the chin. Firstly, the relationship between the midline of the lower incisors and the midline of the chin. If the lower incisor midline coincides with the facial midline, then the chin asymmetry should be corrected by means of a lateral sliding genioplasty. Secondly, the relationship between the facial midline and the chin midline. In cases

where the lower incisor midline coincides with the midline of the chin, the asymmetry should be corrected by means of mandibular surgery. Finally, the presence of a cant of the lower border of the chin. The cant should be related to the interpupillary line and the mandibular occlusal plane and correction of the cant should form part of the lateral correction. Keep in mind that correction of facial asymmetry by maxillary and mandibular surgery, including correction of an occlusal cant, will often also have an effect on the midline of the chin as well as the lower border cant.

4. Chin proportion should be assessed in the frontal plane for transverse and vertical asymmetry. The critical aspect of asymmetry diagnosis of the genial complex is to decide whether the genial complex alone is deviating from symmetry or whether the entire mandible is the cause of the asymmetry (of course a combination of these may also occur). In general if the mandible is asymmetric the lower incisor midline and the genial midline are coincident and correction requires mandibular surgery. If these do not correspond, transverse asymmetry of the chin exists which requires a lateral sliding genioplasty for correction.

Treatment priorities and sequencing the treatment

Before the patient commits to treatment, the treatment plan, the envisaged treatment time of each phase, and the sequence of the steps should be discussed with the patient. To ensure that the dentition and soft tissues are sound, basic restorative dentistry, periodontal treatment, surgical removal of impacted teeth, and bicuspid extractions (when indicated) should be completed before commencement of treatment. Although it may be preferred in some cases to perform surgery early in the orthodontic treatment phase, e.g. class II deep bite cases, it is usually preferable to perform surgery only once good interarch compatibility has been established. This will allow the surgeon to position the jaws more accurately, the teeth will interdigitate better after surgery improving postoperative stability, and in general most patients' enthusiasm and compliance falter after surgery. The postoperative orthodontic phase should not be longer than 3–6 months.

It may be advantageous to place dental implants at the same time as the orthognathic surgery as it will save the patient a second surgical procedure. The authors, however, feel that implants at this stage should be limited to single-tooth implants. The orthognathic surgery stage is an ideal time to perform bone grafting, however, if required for the placement of implants later. This surgical stage also allows for easy intraoral harvesting of bone for grafting. The ideal time for the placement of dental implants is after an orthodontic retention period of approximate-

ly 3 months following band removal. Prosthodontic restoration will enhance orthodontic stability and should be performed as soon as possible.

Visual treatment objective

Many methods of developing a cephalometric treatment objective have been described, varying from hand-drawn orthodontic and surgical changes on an acetate tracing paper, computerized digital predictions, and video imaging techniques.¹⁹ There are three types of visual treatment objectives:

1. A pretreatment orthodontic visual treatment objective. This visual treatment objective is developed from the lateral cephalometric radiograph using all the information gathered from the systematic patient evaluation and database. The orthodontic prediction tracing indicates the required tooth movements and will include: planned extractions, closure of spaces, improving tooth angulations, leveling of occlusal curves where indicated, etc. The prime goal is to place the teeth in a position that will allow the surgeon to achieve the optimal soft and hard tissue results.
2. The pretreatment surgical prediction tracing is developed from the orthodontic prediction tracing. The jaw(s) are now moved and traced in their planned position and the soft tissue changes predicted. The expected soft tissue changes are now evaluated. In cases where an unacceptable esthetic result is achieved on the surgical prediction, the treatment plan should be revised.
3. An immediate presurgical visual objective is created a few days before surgery using the presurgical lateral cephalometric radiograph. Accurate definitive surgical movements are planned and soft tissue changes predicted. The planned dental and skeletal movements are then simulated on articulated dental casts by means of model surgery.

Model surgery

The primary goal of presurgical model surgery is to recreate the patient's jaws and teeth relationship as accurately as possible on an articulator to allow accurate simulation of the intended surgery. The surgical movements as indicated by the surgical cephalometric visual treatment objective are simulated on the articulated cast models and the surgical changes are then recorded. Numerous techniques for model surgery have been described.²⁰ Most techniques involving repositioning of both jaws advocate repositioning the maxilla first and then fabricating an intermediate acrylic splint with the unoperated mandible as a reference. The mandibular arch is now positioned with the teeth in the best occlusion and a final acrylic splint can be fabricated, although the authors very seldom

make use of a final splint. The surgical splint is the key to accurate surgery and thus it is mandatory that model surgery is performed accurately and special care taken during fabrication of the splint.

Surgical technique

Our knowledge and understanding of all aspects of orthognathic surgery have grown over the past 3 decades. At the same time numerous surgical techniques have been developed and refined which enable the modern orthognathic surgeon to treat most complex dentofacial deformities with confidence. The three surgical techniques currently used for the correction of dentofacial deformities, with various modifications, are the bilateral sagittal split ramus osteotomy of the mandible, the Le Fort I maxillary osteotomy, and the genioplasty.

Following the formulation of a treatment plan accurate surgery is required to ensure a successful treatment outcome. Good surgical technique involves the following:

1. Proper treatment planning. The surgeon should be guided by a comprehensive treatment plan including accurate cephalometric, surgical visual treatment objectives and model surgery.
2. Surgical routine. The surgeon should develop a specific routine for each procedure. By following the same sequence (step by step) it will enable the assistants to anticipate each subsequent step, thus increasing efficiency, and decreasing operating time and ultimately patient morbidity. The surgeon should have a clear understanding of each surgical step, the complications that may arise from each step, and the management of each complication.
3. Instrumentation. A myriad of surgical instruments has been designed, all to help the surgeon to eventually achieve the same goal. It is, however, recommended that the surgeon only use a small select group of "favorite" instruments: it is less confusing to both the surgeon and the surgical team.

Bilateral sagittal split ramus osteotomy

Surgical repositioning of the mandible was first described by Blair in 1907;²¹ however, the first report of splitting the mandibular ramus in a sagittal direction was by Trauner and Obwegeser in 1957,²² and also in 1961 by Dal Pont.²³ This technique underwent several modifications over the years.^{24,25} Surgical repositioning of the mandible has now developed from a potentially life-threatening procedure to outpatient surgery (in some parts of the world). The advent of rigid fixation has made postoperative recovery safer and much more comfortable for patients. It is not the intention to describe the surgical

procedure in detail as in a surgical manual, however a short overview in a step-by-step fashion with notes regarding recommendations, possible complications, and their management is provided. For more in-depth discussion on the detail of the surgical technique the reader is referred to text specifically describing surgical technique.²⁶⁻²⁸

1. Soft tissue infiltration with vasoconstrictor. To assist in intraoperative control of hemorrhage, all areas of dissection are infiltrated with vasoconstrictor (epinephrine at a concentration of 1:80 000), 10 minutes before surgery.
2. Soft tissue incision. The soft tissue incision is made through mucosa, muscle, and periosteum, starting superiorly halfway up the mandibular ramus, just lingual to the external oblique ridge carrying the incision downwards ending mesial to the second molar. Leave at least 5 mm of non-keratinized epithelium buccally at the lower end for ease of suturing later.
3. Subperiosteal dissection. Dissection of the periosteum should be limited only to areas where the osteotomies will be performed and muscle attachments that need to be separated from the bone to facilitate bone repositioning and ensure postoperative stability. Take special care during lingual dissection not to damage the inferior alveolar nerve. It is, however, mandatory that the lingula and entrance of the nerve at the foramen be positively identified. The dissection should be decisive, clean, and neat, and should remain under the periosteum at all times.
4. Perform the osteotomies. The sagittal osteotomies can be divided into three parts:
 - The medial ramus osteotomy. Use a 701 fissure bur and aim at the notch of the lingula and terminate the osteotomy in the fossa just posterior of the lingula (Fig. 46.44a). When the osteotomy is terminated short of the lingula, the bone will tend to split anterior to the foramen, leaving the lingula and superior part of the alveolar canal (including the nerve) attached to the proximal segment during the splitting procedure. If this happens the canal should be carefully dissected from the proximal segment, but this will increase the sensory morbidity of the inferior alveolar nerve.
 - The vertical section. Start superiorly at the medial osteotomy, stay just inside the buccal cortex, and end the osteotomy mesial to the second molar.
 - With a channel retractor in place, start the buccal osteotomy at the lower border of the mandibular body, and join it superiorly at the vertical osteotomy. The buccal cortex should be perforated, but take care not to damage the inferior alveolar nerve. Ensure that the lower part of the lingual cortex is included in the inferior osteotomy (Fig. 46.44b).

Fig. 46.44 The surgical design of the bilateral sagittal split ramus osteotomy. (a) The horizontal osteotomy on the medial side of the ramus should extend to just posterior of the lingula into the fossa posterior to the entrance of the inferior alveolar nerve. (b) Ensure that the vertical osteotomy on the lateral side of the body extends to include the lingual cortex. (c) A reference mark across the vertical osteotomy to assist in realignment of the segments. (d) Holes placed for the holding wire, distal on the proximal segment and anterior on the distal segment. (e) A purchase hole placed low down on the proximal segment to facilitate condylar positioning. (f) The stylomandibular ligament is stripped from the angle. (g) The medial pterygoid muscle attachment is stripped from the angle.

Fig. 46.45 Failure to incorporate the lingual cortex at the lower border when performing the vertical osteotomy may result in: (a) fracture of the buccal plate or (b) fracture of a large part of the proximal segment including the coronoid process. (c) Fracture of the lingual part of the distal segment may occur as a result of indiscriminate surgery or the presence of an impacted third molar tooth. (d) A fracture short of the inferior alveolar foramen may occur as a result of the horizontal osteotomy being performed short of the lingula.

5. Place reference marks. To ensure correct alignment of the bone segments during fixation, reference marks are placed on the buccal cortex on either side of the vertical osteotomy (Fig. 46.44c).
6. Place the holes for a holding wire. The authors prefer the use of holding wires during placement of rigid fixation. The holes are placed anteriorly through the buccal cortex of the proximal segment and posteriorly through the lingual cortex of the distal segment. The vector of the holding wire will tend to pull the proximal segment posteriorly (enhancing seating of the condyle) and the distal segment anteriorly (supporting the occlusion) during the placement of rigid fixation (Fig. 46.43d). A bone clamp or condylar positioner may be used as an alternative. It is, however, mandatory not to force the segment together with the clamp
7. Place the hole for the condylar positioner. The hole is placed low down on the buccal cortex of the proximal segment using a small round drill. The hole will serve as a purchase point for the condylar positioner during condylar positioning and tightening of the holding wire (Fig. 46.43e).
8. Splitting the mandible. The actual splitting of the mandible can be divided into two stages. The first stage involves the initiation of the split. A 10 mm thin but rigid osteotome is used to tap along the vertical osteotomy line. Keep the osteotome parallel to the buccal cortex and support the mandible at the inferior border with the channel retractor preventing any damaging forces to the condyle.

During the first stage the surgeon should see the proximal segment separate from the distal segment at the lower border and see that the neurovascular bundle is intact and separates from the proximal segment. In the second stage the split is completed. The surgeon places a large osteotome superiorly into the vertical osteotomy and a small Reyneke sagittal splitter low down into the buccal osteotomy. Rotate both instruments and visualize that the lower border continues to split towards the proximal segment, the neurovascular bundle detaches from the proximal segment as the split continues, and the inferior alveolar foramen and proximal part of the canal detach from the proximal bone segment. If the neurovascular canal does not detach from the proximal segment, the splitting procedure should be stopped and the bundle very carefully dissected from the bone. An unfavorable split can be avoided by meticulously adhering to the surgical steps. It is advisable, in cases where the split does not proceed favorably, to stop the procedure and identify the problem. It is much easier to salvage the split if the potential problem is diagnosed early. The following are unfavorable splits that may mostly occur:

- Fracture of the buccal cortex of the mandibular body. Problem: failure to complete the buccal osteotomy at the inferior border and to include the lingual cortex in the osteotomy. Solution: redefine the osteotomy at the lower border and recapture the inferior part of the segment to be included in the buccal cortex of the proximal segment (Fig. 46.45a).
- Fracture of the buccal cortex involving body and ramus of the mandible. Problem: failure to

Fig. 46.46 The condylar positioner is engaged into the purchase hole and, by digital pressure on the mandibular angle, the condyle is carefully pushed backward and superiorly to seat the condyle into the glenoid fossa. At the same time the reference marks are used to ensure proper alignment of the lower borders of the segments. The holding wire is then tightened. The wire assists the surgeon to place rigid fixation without the burden of holding the segments in position during placement of rigid fixation.

- include the lingual cortex in the buccal osteotomy and only diagnosing the problem near completion of the split. The fractured segment may include the coronoid process. Solution: redefine the buccal osteotomy at the lower border and recapture the buccal cortex at the lower border (Fig. 46.45b).
- Split on the medial aspect of the ramus running anterior to the lingula. Problem: the horizontal osteotomy on the medial aspect of the mandibular ramus was performed short of the lingula. Solution: redefine the medial osteotomy and extend it past the lingula. Carefully dissect the lingula and nerve from the proximal segment (Fig. 46.45c).
 - Fracture of the retromolar segment of the distal segment. Problem: usually occurs when an impacted third molar tooth is present in the area. Solution: it is advisable to remove impacted third molar teeth 9 months before orthognathic surgery is performed, however if a fracture does occur remove the tooth and use a bone plate as method of fixation (Fig. 46.45d).
9. Stripping the pterygomasseteric sling. Place a curved periosteal elevator (J-stripper) around the lower border of the distal segment and strip the muscle fibers of the masseter and pterygoid muscles from the segment. This will allow free movement of the distal segment.
 11. Smoothen the contact areas between the bone segments. Sharp alveolar bone spicules may damage the inferior alveolar nerve following bone approximation. Smoothening of the bone will also facilitate good bone contact during fixation.
 12. Placement of intermaxillary fixation. Maxillo-mandibular fixation is applied with the teeth in the planned occlusion. A prefabricated splint may be used when necessary.
 13. Removal of bone from the proximal segment. In mandibular setback cases there will be an overlap between the two bone segments. Remove the overlapping bone from the proximal segment and take care not to damage the inferior alveolar nerve.
 14. Condylar positioning. Positioning the condyle into its correct relationship to the glenoid fossa is challenging and probably the most important step of the procedure. Place the condylar positioner into the hole drilled at the lower border of the proximal segment (step 7) and while supporting the mandible by digital pressure at the angle, carefully push the condyle backwards and superiorly into the glenoid fossa (Fig. 46.46). An awareness of the anatomic relationship between the condyle and the fossa will assist the surgeon in this important step. Problem: excessive force on the proximal segment during this maneuver could displace the articular disc, lead to hemarthrosis or joint effusion, or push the condyle too far superiorly or posteriorly. The return of the condyle to its natural fossa relationship following placement of rigid fixation and release of intermaxillary fixation is called condylar sag. The change in the condylar position will lead to an apparent incorrect occlusion.²⁹ Solution: the surgeon should be able to diagnose condylar sag intraoperatively and, if it does occur, the rigid fixation should be removed and the condylar positioning step repeated.
 15. Tightening the holding wire. Use the condylar positioner and gently hold the condyle in the desired position and ensure that the reference marks (placed step 5) line up. The assistant can now tighten the holding wire by twisting the wire carefully so as not to force the segments together.
 16. Placement of rigid fixation. Bicortical screws are now placed through an intraoral approach or by an extraoral approach (using the relevant trochar). The bone segments can also be fixated by means of bone plates and unicortical screws.

17. Evaluating the occlusion. Remove the intermaxillary fixation and pull the mandible forward and laterally to allow the condyle to "settle" into its position. The occlusion is now checked by opening and closing the jaw.²⁹ In cases where a surgical splint is used the teeth should fit into the split without force.
18. Intra- and extraoral sutures. The incisions are now closed by using 3/0 chromic sutures intraorally and a 5/0 nylon suture extraorally.
19. Place intermaxillary elastics. A triangular, vertical, ¼ inch, 4 oz (6 mm, 113 g) elastic is placed in the canine region bilaterally.
20. Apply a pressure bandage. A pressure bandage for the control of postoperative swelling should remain on the face for 2 days following surgery. Physical therapy should follow removal of the pressure bandage to assist in mouth opening and reduction of swelling. The patient is referred back to the orthodontist after about 3 weeks with the elastics in place.

Genioplasty

The chin is one of the most noticeable facial structures and correction of chin deformities demands an artistic approach. The sliding genioplasty can be performed as an isolated procedure or in conjunction with other orthognathic procedures. Genioplasty is, however, not a substitute for the surgical advancement of the mandible. The osteotomy is performed at the anterior part of the inferior border of the mandible and its versatility enables the surgeon to modify the genial area in all three dimensions.³⁰ As with all surgical procedures the genioplasty procedure should be performed following appropriate treatment planning and in a step-by-step fashion.³¹

1. Infiltration with vasoconstrictor. The area of dissection is infiltrated with local anesthetic containing vasoconstrictor (epinephrine at a concentration of 1:80 000) 10 minutes before surgery.
2. Incision. The first incision is made through the mucosa only from just distal to the canine to a similar point on the contralateral side and at least 5 mm away from the attached gingival margin. Branches of the mental nerve can often be identified laterally and should be avoided. The second incision is made through the periosteum on to bone.
3. Mucoperiosteal dissection. Start the subperiosteal dissection in the center and dissect laterally to identify the mental nerves on each side.
4. Mark the reference points. Use a 701 drill and place horizontal and, if required, vertical reference marks in the center and laterally on the buccal cortex.
5. Osteotomy design. The chin shape and the position of pogonion can be altered three-dimensionally by changing the design of the osteotomy. Most

genioplasty procedures are performed to improve the antero-posterior dimensions of the chin, however by changing the angulation of the osteotomy a plane is created along which the segment will slide (Fig. 46.47). The variation of the angle of the osteotomy will lead to changes in the vertical dimension of the anterior mandible with obvious esthetic consequences. The height of the osteotomy is influenced by the roots of the incisor and canine teeth as well as the position of the mental foramen. Keep in mind that the nerve exit at the foramen is approximately 5 mm above the nerve canal containing the nerve. The transverse dimension of the chin can be altered by segmentalizing the genial segment. The width of the anterior part of the chin is altered by an ostectomy in the symphysis area while the posterior area is altered by performing an osteotomy in the center of the chin and then rotating the segments inward or outward (Fig. 46.48). The vertical dimension can be changed by either downgrafting the segment or by performing an ostectomy and then superior repositioning the segment.

6. Osteotomy of the chin. The osteotomy is performed with an oscillating saw by starting at the center and cutting laterally.
7. Placement of a holding wire. Drill a hole through the buccal cortex in the center of the segment and feed a 018 inch (0.065 mm) wire through the hole. The wire is helpful during mobilization and accurate positioning of the segment.
8. Repositioning the chin. By using the holding wire and extraoral digital pressure, the chin is now placed into the planned position.
9. Rigid fixation of the chin. The segment can be fixated either by means of two screws engaging the segment and both cortices of the symphysis of the mandible or by utilizing bone plates (Fig. 46.49a, b).
10. Suturing. The wound is sutured in two layers. Ensure accurate reapproximation of the mentalis muscles by using 3/0 chromic sutures followed by symmetrical suturing of the mucosa using 4/0 sutures.
11. Pressure bandages. To prevent swelling and hematoma formation, a pressure bandage is

Fig. 46.47 By varying the angle of the genioplasty osteotomy, (1) the height of the chin can be altered when (2) the chin is repositioned horizontally.

placed over the surgical area. The bandages should remain in place for 3–4 days.

Le Fort I maxillary osteotomy

The first Le Fort I osteotomy was performed in Germany by von Langenbeck in 1859 for the removal of nasopharyngeal polyps.³² Cheevers described performing a Le Fort I osteotomy in 1867 using chisels to gain access to the nasal cavity.³³ The first time that a Le Fort I osteotomy was used for the surgical correction of a facial deformity was by Wassmund in 1927.³⁴ Over many years the precision of the operative technique and establishment of a scientific and biological basis for the procedure has been established.^{35,36,37} The Le Fort I osteotomy has become an essential procedure in the surgical armamentarium of the oral and maxillofacial surgeon for the correction of dentofacial deformities.

Fig. 46.48 The posterior width of the chin can be altered by performing a midline osteotomy and narrowing the chin by removing a segment of bone (a), or widened by outward rotation of the segments (b). A bone plate is placed on the chin before the segment is mobilized.

Fig. 46.49 (a) Following advancement of the chin the segment can be immobilized by tricortical fixation. (b) Plate fixation is usually preferred following posterior repositioning of the chin.

1. Soft tissue infiltration with vasoconstrictor. To assist in intraoperative control of hemorrhage, the areas of the proposed incision are infiltrated with vasoconstrictor (epinephrine at a concentration of 1:80 000) 10 minutes before surgery.
2. Soft tissue incision. The initial soft tissue incision is made through mucosa and positioned at the superior depth of the maxillary buccal sulcus, starting from the level of the second premolar, proceeding anteriorly and inferiorly to just below the anterior nasal spine. The incision is repeated and deepened to include muscle and periosteum. Care must be taken not to extend the incision beyond the second premolar or to place it in the attached mucosa as this will compromise an important source of blood supply for the down-fractured maxilla.
3. Subperiosteal dissection. Dissection of the periosteum begins by elevating the periosteum on the superior aspect of the incision. (Periosteal coverage of the maxilla should be maintained unless interdental osteotomies are planned, in which case limited periosteal elevation over the areas of interdental osteotomy is required.) Periosteal reflection proceeds to expose the posterior lateral wall of the maxillary sinus taking care not to perforate the periosteum as this will result in herniation of the buccal fat pad.
4. Reflection of nasal mucosa. Similarly, the nasal mucosa is reflected off the nasal floor and medial and lateral walls as superiorly as possible to allow osteotomies to be performed without lacerating the nasal mucosa.
5. Perform the osteotomies of the lateral walls of the maxillary sinus (Fig. 46.50). The Le Fort I osteotomy may be designed as either a stepped osteotomy parallel to the occlusal plane (if only

Fig. 46.50 When performing a stepped osteotomy: (1) the anterior osteotomy is performed first extending from the piriform rim to the zygomatic buttress, followed by (2) a vertical osteotomy at the buttress, and then (3) completing the osteotomy posteriorly at the maxillary tuberosity.

antero-posterior movements are required) or a straight osteotomy diverging from the occlusal plane anteriorly (if vertical movements are required). Before commencing the osteotomy the surgeon must orientate the height and angle of the proposed osteotomy, taking into account the esthetic requirements, the presurgical planning, the anatomical landmarks which guide the osteotomy and those to be avoided.^{38,39} The osteotomy is performed from the nasal rim and extended posteriorly to the zygomatic buttress. The step is then performed perpendicular to the first osteotomy running along the zygomatic buttress and continuing along the posterior lateral maxillary sinus wall to the limit of visual access. The step allows the surgeon to perform the osteotomy parallel to the occlusal plane. If a straight osteotomy is required it is a posterior continuation of the anterior osteotomy. If any vertical reduction is planned for, a second osteotomy parallel to the

first is completed at a distance determined by the preoperative planning (Fig. 46.51).

6. Place the holes for a holding wire. Holes are placed above and below the osteotomy slightly anterior and posterior to the zygomatic buttress to allow the placement of a zygomatic buttress wire.
7. Lateral nasal wall osteotomy. The lateral nasal wall is sectioned with the appropriate osteotome until the resistance of the pterygoid plates is felt.
8. Pterygoid plate osteotomy. Separation of the posterior maxilla from the pterygoid plates is completed with the appropriate osteotome positioned to engage the cleft that can be felt inferior to the pterygo-maxillary fissure. With the surgeon placing a palpating finger intraorally on the pterygoid hamulus and holding the osteotome with the other hand, the assistant percusses the osteotome until the surgeon feels the separation of the pterygoid plates intraorally. The lateral wall osteotomy

Fig. 46.51 By changing the design of the Le Fort osteotomy various geometric effects can be achieved. (a) When only maxillary advancement is required a stepped osteotomy is preferred to allow the surgeon to perform the osteotomy parallel to the occlusal plane. Advancement of the maxilla along this plane will not alter the vertical dimension. (b) Patient with more severe midface deficiency may require a high Le Fort I osteotomy. (c) Patients with maxillary antero-posterior and vertical deficiency would benefit from a Le Fort I down sliding technique. The osteotomy is performed at an angle to allow the maxilla to slide inferiorly as it is advanced. (d) If the maxilla only requires superior repositioning a straight osteotomy is performed.

is then completed with an appropriate osteotome, again carefully advancing posteriorly until the resistance of the pterygoid plates is felt.

9. Interdental osteotomies. If these are required they are performed at this stage. The periosteum is reflected in the area of the osteotomy, and the root angulations are visualized as well as possible. The osteotomy is commenced with a fine drill commencing from the Le Fort I osteotomy cut 5–6 mm lateral the piriform rim and continued inferiorly between the roots to the apex of the alveolus. This initial cut must extend no deeper than the buccal cortex. A fine osteotome is then used to complete the osteotomy through to the palate. The surgeon positions the osteotome and palpates intraorally for palatal cortex perforation while the assistant carefully percusses the osteotome until the surgeon is satisfied that the palatal osteotomy has been completed.
10. The above procedures (1–9) are repeated on the contralateral side
11. Nasal septal osteotomy. The remaining nasal mucosa is reflected off the septum and the septum is sectioned off the nasal surface of the septum with the appropriate osteotome.
12. Down fracture. The maxilla is down fractured by digital pressure applied to the anterior teeth forcing the maxilla inferiorly. If the down fracture cannot be completed, all the previously performed osseous cuts should be revised.
13. Maxillary mobilization. To passively position the maxilla, it is critical that any residual bone attachments at the pterygo-maxillary junction be severed and the adherent soft tissues are stretched. This is accomplished by means of the appropriate osteotome positioned behind the maxillary tuberosity and the careful application of an anteriorly directed force to the maxilla, taking care not to tear the lateral soft tissue pedicles of the maxilla.
14. Refinement of osteotomy edges. Any jagged edges of bone on the lateral and medial sinus walls are removed.
15. Bone reduction of the posterior maxilla (Fig. 46.52). If superior repositioning of the maxilla is required then the appropriate amount of bone needs to be removed. If possible this should be performed predominantly on the posterior of the down fractured maxilla as it is less likely to damage important blood vessels posterior to the pterygoid plates when significant hemorrhage would be encountered. With large impactions however, bone removal is also required from the pterygoid plates and into the pterygomaxillary fissure. This should be done judiciously and with great care.
16. Reduction of nasal sill and perpendicular plate of the palatine. If anterior or superior repositioning is envisaged then reduction of the nasal sill is required (more for the latter) to obviate against negative esthetic nasal changes. Moreover to prevent septal buckling the requisite amount of septal reduction from the nasal floor is required.
17. Segmentation. If planned, the necessary segments are completed from the superior aspect of the palate and alveolus.
18. Place intermaxillary fixation. The maxilla is secured to the mandible either directly or via a splint with stainless steel wires.
19. Placement of buttress wires. If these are to be used for fixation at the buttress then they are placed now. Multipiece maxillary surgery and downgrafting require rigid fixation at the buttress and in such cases the placement of a buttress wire is omitted.
20. Maxillary positioning. The maxillomandibular complex is now positioned, ensuring that the mandibular condyles are seated and the maxilla achieves the desired position.
21. Application of rigid fixation. With the maxilla in position and held either by buttress wires or manually, titanium plates are adapted to the piriform rims and buttresses and secured with screws.
22. Grafting of defects. At this stage any defects present due to either downgrafting or large advancements should be grafted.
23. Checking of occlusion. The intermaxillary fixation is removed and the mandible allowed to find its neutral condylar position. Light digital pressure on the menton is used to approximate the mandible to the maxilla. Should the occlusion not correspond to the preplanned occlusion, the maxilla should be released, repositioned following reapplication of the maxillomandibular fixation, and resecured.
24. Cinch suture. Negative nasal changes (widening of the nasal base and lifting of the nasal tip) particularly following maxillary advancement and superior repositioning, can be counteracted by the placement of a cinch suture.
25. Soft tissue closure. The incision is closed in layers, first approximating the facial muscles and thereafter mucosal closure is completed.

Fig. 46.52 Bone should be removed from the posterior part (tuberosity) of the down fractured maxilla when required. This will avoid damage to important anatomical structures behind the pterygoid plates.

26. Place intermaxillary elastics. A triangular, vertical, ¼ inch, 4 oz (6 mm, 113 g) elastic is placed in the canine region bilaterally.
27. Apply a pressure bandage. A pressure bandage for the control of postoperative swelling should remain on the face for 2 days following surgery. Physical therapy should follow removal of the pressure bandage.

Simultaneous orthognathic surgery and rhinoplasty

The nasal airway is often obstructed with mucus, edema, nasal packing, and blood clots following nasal reconstruction. With the use of rigid fixation the oral airway can, however, be maintained enabling the surgeon to perform certain rhinoplasty procedures concurrent to orthognathic surgery. The orthognathic procedures are first completed whilst the patient is intubated via the nasotracheal route. This is then changed to an oral endotracheal tube to facilitate the rhinoplasty procedure. Rhinoplasty should not be performed as the first surgical procedure. The Le Fort I maxillary osteotomy allows for excellent access to internal nasal structures and procedures such as turbinectomy, septoplasty, and removal of nasal polyps.

Certain maxillary procedures, such as superior repositioning and advancement of the maxilla, have a tendency to affect the shape and size of the nose and paranasal anatomy. Control of these effects requires trimming of the septum, contouring of the piriform rims, and placement of a cinch suture. The authors prefer not to correct external nasal deformities at the same time as Le Fort I maxillary osteotomies but rather to defer it as a secondary procedure. Harvesting of nasal septal cartilage for the use of grafting at a secondary rhinoplasty procedure is easily performed during the orthognathic surgery procedure with the maxilla in the down fractured position. The harvested cartilage can be "stored" by suturing it under the buccal mucosa following the Le Fort I procedure and can be recovered at the time of nasal surgery. When only lower jaw surgery is performed, rhinoplasty can be safely performed concurrently as no absolute nasal effects are to be expected from mandibular surgery.

Chapter 47

Orthognathic Surgery in Obstructive Sleep Apnea

Scott B. Boyd

The objective of this chapter is to provide guidelines for the evaluation of patients with obstructive sleep apnea (OSA) and their treatment with orthognathic surgery. Evaluation of the patient to confirm the diagnosis is an important issue and different diagnostic tools are listed. The principles of treatment and alternative methods are discussed in the chapter. Maxillomandibular advancement in adults is the clinically most effective application of orthognathic surgery for treatment of OSA. A treatment protocol for children with OSA is also included in the chapter.

Introduction

Orthognathic surgery is most commonly used to correct developmental or acquired maxillofacial skeletal deformities (MSD). Over the past two decades, orthognathic surgery has increasingly been used for the surgical treatment of individuals with obstructive sleep apnea (OSA). Although similar orthognathic surgical techniques are used, there are multiple important differences that exist between MSD and OSA patients. It is essential for the treating surgeon to understand these differences to facilitate

effective and safe surgical care for the OSA patient. Important differences between the two groups include: goals of therapy, patient profile, underlying medical conditions, and magnitude of surgical movement. Most MSD patients are adolescents or young adults in good general health. In contrast, the typical OSA patient is a middle-aged, obese male, with significant comorbid medical conditions. The OSA patient has anatomic abnormalities of the upper airway and larger surgical movements (10mm or greater) of the mandible and maxilla are routinely required to effectively treat obstruction of the upper airway during sleep.

The major objective of this chapter is to provide practical guidelines for the evaluation of patients with OSA, and treatment by orthognathic surgery. These guidelines are based on a critical review of the current literature and the author's personal experience. The presentation will focus on maxillomandibular advancement (MMA) for adults, as this is the most common and clinically effective application of orthognathic surgery to treat OSA. Adolescents can be treated using essentially the same protocol. In children the etiology of OSA and surgical treatment differ from those for adults and an overview of management of the pediatric patient will be provided.

Obstructive sleep apnea

Epidemiology and pathophysiology

OSA is a common primary sleep disorder that occurs in up to 9% of women and 24% of men aged 30–60.¹ Middle-aged, obese males are individuals most at risk to develop OSA. OSA is a condition characterized by repetitive partial or complete upper airway collapse during sleep. The ensuing reduction in airflow leads to hypoxia and subsequent arousals from sleep, producing sleep deprivation. The major symptoms of OSA are excessive daytime sleepiness, loud snoring, witnessed stop-breathing episodes, and non-restorative sleep. The effect that OSA has on general

health and well-being has been well documented.^{2,3} OSA is associated with hypertension,⁴⁻⁶ cardiovascular disease,⁷⁻¹⁰ metabolic syndrome,^{11,12} stroke, and possible premature death.¹³ There is a reduction in quality of life,^{14,15} including diminished social function and an increased rate of motor vehicle accidents.¹⁶ Deficits in neuropsychological functioning occur, including diminished vigilance, executive functioning, and motor coordination.¹⁷

Diagnosis and definitions of OSA

Nocturnal polysomnography (PSG) is the established standard technique to objectively diagnose OSA.^{18,19} PSG evaluates sleep disordered breathing (SDB), sleep architecture, and oxygen desaturations. The primary measure of SDB is the apnea-hypopnea index (AHI) which is the number of apneas and hypopneas per hour of sleep. An apnea is defined as an interruption of airflow lasting at least 10 seconds in adults or the equivalent of two breaths in children. A hypopnea is a specified reduction in airflow and an associated oxygen desaturation or arousal, lasting at least 10 seconds in adults or the equivalent of two breaths in children. The AHI is the primary measure used to determine the severity of OSA and effectiveness of treatment. OSA is classified as mild (AHI = 5–15), moderate (AHI = 15–30), and severe (AHI > 30).^{18,19}

Principles of treatment

Treatment strategies for OSA include both non-surgical and surgical forms of therapy. Most treatment protocols are designed to open the upper airway at the site of obstruction, while other modalities of therapy treat the associated obesity (e.g. weight loss, bariatric surgery). Surgical treatment is directed towards site-specific anatomic modification of the upper airway with the goal to prevent or diminish obstruction by pharyngeal collapse. Most surgical procedures attempt to treat the obstruction by one of three methods: (1) removal or reduction in size of excessive pharyngeal soft tissue structures; (2) expansion of the surrounding facial skeletal framework; or (3) bypass of the upper airway.

Continuous positive airway pressure

Nasal continuous positive airway pressure (CPAP) is considered the first and most effective form of therapy to treat OSA in adults.²⁰ CPAP is administered via a mask during the night to splint open the airway, leading to reductions in arousals, decreased sleep fragmentation, and resolution of sleep deprivation. CPAP has been shown to be highly effective treatment in individuals with moderate and severe OSA. Significant improvements in objective and subjective daytime sleepiness, quality of life, and cognitive function have been demonstrated following the use

of CPAP.^{20,21} Some studies have also shown that CPAP leads to a decrease in blood pressure and other cardiovascular events.²¹ Although CPAP has been shown to be highly effective, virtually eliminating OSA, long-term acceptance and adherence to therapy are relatively low. Reports indicate that as many as 46–83% of OSA patients are non-adherent to therapy.²² CPAP also requires lifetime nightly use.

Oral appliance

Oral appliances (OAs) are a non-surgical alternative to CPAP and may be indicated in some patients who are not able to tolerate CPAP. An OA is a device that the patient wears during sleep, that positions the mandible forward (about 10mm) for the purpose of increasing the posterior airway space. OAs are less effective than CPAP and are recommended primarily for individuals with mild to moderate apnea.^{23,24} Therapy is more effective in less obese patients and individuals who have certain craniofacial features (e.g. mandibular retrognathia).²⁵

Weight loss/bariatric surgery

Obesity is positively associated with OSA and even modest weight loss has been shown to decrease OSA. A 10% weight gain predicts about a 32% increase in AHI, while a 10% weight loss results in a 26% decrease in AHI.²⁶ Unfortunately, treatment of obesity by a structured program of weight loss shows high rates of failure and relapse with more than 90% of patients unable to maintain a 5–10% decrease in weight for more than 5 years.^{27,28} Bariatric surgery has recently emerged as an effective long-term treatment for weight reduction, as well as an effective treatment for reducing OSA, in morbidly obese patients.^{27,29} For OSA patients, bariatric surgery should be considered for those individuals with a body mass index (BMI) greater than 35.²⁹

Tracheostomy

In the past, tracheostomy was selected as the most viable of the surgical options. Similar to CPAP, it has a high level of success in eliminating OSA.³⁰ However, it has significant drawbacks in that it may increase psychosocial problems. Tracheostomy is generally reserved for those patients with severe apnea and concomitant severe cardiovascular symptoms requiring urgent correction of significant hypoxemia.

Uvulopalatopharyngoplasty

Uvulopalatopharyngoplasty (UPPP) has become the most widely used surgical procedure to treat OSA. UPPP involves the removal of tissue from the soft palate, uvula, and lateral pharyngeal walls in order to create a more open upper airway. UPPP has shown improvements in snoring and other subjective symp-

toms,^{31,32} but a relatively low rate of improvement in SDB. Unfortunately UPPP is effective in only about 41% of patients with OSA.³³ In addition to low response rates, initial improvements that do occur may diminish over time.^{34,35} Patients with mild to moderate apnea tend to have much greater responsiveness than those with severe apnea and UPPP is more effective in patients with a lower BMI.^{33,36} In some patients, OSA can actually become worse after UPPP.³⁷

Maxillomandibular advancement

One of the most successful surgical procedures in the treatment of OSA is maxillomandibular advancement (MMA). MMA involves surgical facial advancement, by performance of concomitant maxillary and mandibular osteotomies, for the purpose of creating an enlarged posterior airway space (Fig. 47.1). In general, MMA surgery yields high success, and is considered to be the most effective treatment aside from CPAP and tracheostomy.³⁸ Reported short-term success rates for MMA range from 65–100%.^{39–42} It appears that the initial improvements in SDB following MMA may be maintained on a long-term basis.^{43,44}

Some surgeons have approached MMA as a stand-alone procedure,^{42,45,46} while others have advocated a staged approach to treatment.⁴⁰ In the staged protocol, a patient diagnosed with OSA will first undergo “phase I” surgery, which includes UPPP and possibly concomitant adjunctive procedures. These adjunctive procedures may include genial advancement, hyoid repositioning, tonsillectomy and adenoidectomy, tongue base surgery, and nasal surgery. If phase I surgery is not clinically effective, the patient would proceed to “phase II” surgery consisting of MMA.

Fig. 47.1 Maxillomandibular advancement procedure consisting of LeFort I maxillary osteotomy with step modification, bilateral sagittal split ramus osteotomies, and genial advancement; stabilized with bone plate fixation. Shaded area depicts sites of anterior nasal spine reduction and piriform rim recontouring. (Adapted from Boyd SB. Management of obstructive sleep apnea by maxillomandibular advancement. *Oral Maxillofac Surg Clin North Am* 2009; 448, with permission.)

Currently it is unknown whether staged surgery provides any benefit over isolated MMA.

Patient evaluation

The purpose of the initial surgical consultation is to confirm a diagnosis of OSA and to determine if the patient is a candidate for orthognathic surgery. Commonly, the patient has already been evaluated by a sleep specialist and has undergone objective evaluation, by polysomnography, to establish a diagnosis of OSA. Furthermore, it is likely that the patient has already attempted to use CPAP. If this initial evaluation and treatment have already occurred, the surgeon should confirm the findings, otherwise an overnight sleep study will need to be obtained to objectively establish a diagnosis of OSA, prior to initiating any treatment.

Major components of the evaluation include a comprehensive history, sleep study, clinical examination, and imaging studies. Most of the evaluation is similar to a routine orthognathic surgery consultation, with the addition of components specific to OSA.

Symptoms and history

A thorough sleep-specific history and comprehensive medical history are essential components of the evaluation. Important elements of the sleep history include: presence and character of snoring, level of daytime sleepiness, self-reported or observed nocturnal episodes of breathing cessation, and the perceived quality and quantity of sleep. Valid and reliable measurement tools to evaluate sleepiness and quality of life in OSA patients are available.⁴⁷ The Epworth Sleepiness Scale (ESS) is an eight-item questionnaire that is commonly used to subjectively assess the patient's level of daytime sleepiness.^{48,49} The patient may also relate a variety of symptoms related to a decreased quality of life, such as poor job performance, decreased ability to concentrate, memory loss, and fatigue. The Calgary Sleep Apnea Quality of Life Index (SAQLI)^{50,51} and the Functional Outcomes of Sleep Questionnaire (FOSQ)⁵² are two valid and reliable sleep-specific quality-of-life questionnaires that may be used.

The patient should also be questioned about previous treatment of OSA and past response to therapy. This should include both the patient's subjective and objective (e.g. post-treatment PSG) response to therapy. Patients should also be questioned about any treatment-related adverse outcomes or complications of previous therapy.

A comprehensive medical history must be obtained because OSA is associated with a wide spectrum of medical conditions (e.g. cardiovascular disease, metabolic syndrome, psychiatric disease) that may affect surgical treatment and the patient's overall health. If there is presence or a suspicion of a significant medical condition, it will be important to

obtain indicated consultations to establish the status of the disease, determine if the patient is a candidate for surgery, determine what can be done to optimize the patient's condition prior to surgery, and to obtain recommendations for intraoperative and postoperative management of the patient with regard to each significant medical condition. This assessment is essential to determine the risk/benefit ratio for surgical intervention. One of the most common medical conditions is hypertension and it is important to optimize blood pressure preoperatively, since patients will typically have modified hypotensive anesthesia administered during surgery.

Polysomnography

When the initial consultation appointment is scheduled, the patient should be instructed to send (or bring with them to the consultation visit) the reports of all previous sleep studies. These reports are essential to establish the presence and severity of OSA. It is likely that the patient has had a CPAP titration performed and the titration results will give an indication of the effectiveness of CPAP if the patient is compliant with CPAP therapy. Furthermore, if the patient has undergone treatment of OSA, post-treatment sleep studies may have been completed to assess the result of therapy. The most recent sleep study should accurately reflect the patient's current status. If significant time has elapsed since the last study and/or the patient's symptoms (e.g. daytime sleepiness) have significantly changed (especially worsened), a repeat sleep study is indicated to accurately assess the current severity of OSA.

Physical examination

A comprehensive head and neck examination should be performed for each patient. This physical examination should include measurement of the patient's BMI, resting blood pressure, and neck circumference. The OSA clinical evaluation is very similar to a routine orthognathic surgery evaluation, with special attention directed to potential sites of upper airway obstruction.

It is important to carefully perform all aspects of the routine orthognathic surgery baseline clinical examination to facilitate surgical treatment planning and to determine if presurgical orthodontic care would be of benefit. The clinical examination should include assessment of temporomandibular joint (TMJ) function and mandibular mobility, occlusion, status of the dentition, neurosensory function, and facial esthetics. For most middle-aged adults, adaptations in the dentition have occurred (e.g. wear and restorations) to maximize occlusal relations of the teeth, and the patient will not significantly benefit from orthodontic therapy prior to surgery.

Important augmented components of the upper airway examination include: inspection of the nasal

cavity to determine sites of possible obstruction, description of the size, character, and function of the tonsils, soft palate, lateral and posterior pharyngeal walls, and base of tongue. In addition to direct visual examination, endoscopic examination (fiberoptic nasopharyngoscopy) of the upper airway may be of benefit to aid in the visualization of the upper airway and identification of the site(s) of pharyngeal collapse and obstruction.

Imaging

A standardized lateral cephalometric radiograph should be taken, with the patient positioned in adjusted natural head position with the mandible in centric relation and the facial soft tissues in repose (Fig. 47.2). A cephalometric analysis is then performed to assist in the identification of potential sites of upper airway obstruction and to characterize craniofacial morphology (Fig. 47.3). If the patient proceeds to surgery, the cephalometric radiograph will be used for both surgical treatment planning and assessment of changes in the facial skeleton and upper airway that occur as a result of surgery. The major limitation of the cephalometric radiograph is that obtaining the radiograph in an upright and awake position may not accurately reflect the anatomic characteristics of the upper airway when the patient is sleeping in a supine position.

Facial and intraoral digital photographs should be taken to document the clinical examination and may be linked to the lateral cephalometric radiograph to develop computerized surgical prediction images (Fig. 47.2). This is important because the magnitude of the surgical movement (10 mm or more of facial advancement) may have a significant impact on facial appearance and the prediction images allow the patient to see the type (not necessarily the actual result) of facial esthetic changes that may occur as a result of surgery.

Computed tomography (CT) imaging has not routinely been used for the surgical treatment of adults with OSA. However, since three-dimensional (3D) CT imaging has recently become available in an outpatient office setting (e.g. cone-beam technology), use of this technology may be beneficial because it has the ability to visualize the entire upper airway and can demonstrate the association between 3D changes in the facial skeleton, as a result of surgery, and the upper airway.

Indications for maxillomandibular advancement

Once the evaluation has been completed, it can be determined if the patient is a surgical candidate. The indications for MMA are as follows: (1) significant OSA (AHI > 15) as objectively diagnosed by PSG; (2) failure of CPAP because of non-acceptance or poor adherence to therapy; (3) craniofacial abnormali-

Fig. 47.2 Frontal facial (a), lateral facial (b), lateral cephalometric radiograph (c), and intraoral (d–f) pretreatment images of a 35-year-old man with severe obstructive sleep apnea (AHI = 49), decreased posterior airway space, retrusive facial profile and normal Class I dental occlusion.

Fig. 47.3 Cephalometric analysis for obstructive sleep apnea with depiction of anatomic landmarks and associated measurements (normal values).

ties (e.g. children with micrognathia); and (4) ability to undergo surgical treatment (consideration of concomitant medical conditions). It is also important to determine if the patient is a candidate for other forms of treatment. For example, if the patient has mild OSA, oral appliance therapy could be considered as a viable non-surgical form of therapy. Bariatric surgery may be considered for the extremely obese patient (BMI > 35). Additionally, it should be determined if the patient is a candidate for surgical-orthodontic care, although this is uncommon.

Presurgical treatment planning

Most of the records necessary to perform definitive presurgical treatment planning may have already been obtained during the initial consultation visit. The results and recommendations of all consultations, obtained after the initial evaluation, should be reviewed. The current status of all significant medical conditions should then be assessed. A final determination can then be made regarding the patient's candidacy for surgery and a detailed discussion of the potential surgical, medical, and anesthetic risks of surgery should occur with the patient.

Complications of surgery in patients with MSDs have been well studied.⁵³ The most common complications observed following surgical correction of a MSD include: neurosensory changes of the lips and chin, infection, skeletal relapse, TMJ disorders, and dental injuries. Age is considered to be the strongest predictor of complications, while large skeletal movements seem to have greater relapse potential.⁵³ MMA patients typically display one or more of these predictors of complications, including older age, large surgical movements, and medical comorbidities that may negatively impact wound healing. Currently, it is unknown whether MMA patients actually experience more complications than MSD patients.

Due to the combined maxillary and mandibular movements and the large magnitude of facial advancement, it is recommended that a facebow transfer and mounting of dental casts on a semi-adjustable articulator be used to provide an accurate 3D positioning of the maxilla and mandible in relation to the TMJ. It is also recommended that model surgery be completed using a model platform to accurately measure the planned surgical movements of the maxilla and mandible, in three planes of space. The final surgical plan will be based on the patient's individual findings, including the presence or absence of a pre-existing dentoskeletal deformity, but a minimum of 10mm of mandibular and maxillary advancement is recommended to produce the most improvement in OSA. In the routine patient, who does not undergo concomitant orthodontic care, the maxilla will move an equivalent distance to the mandible, to maintain the patient's pre-existing occlusal relations.

Fig. 47.4 Model surgery in preparation for maxillomandibular advancement showing interim splint after a 10mm advancement of the maxilla. (From Boyd SB. Management of obstructive sleep apnea by maxillomandibular advancement. *Oral Maxillofac Surg Clin North Am* 2009; 451, with permission.)

Following completion of the model surgery, an interim splint is constructed using the advanced maxillary cast referenced to the uncut mounted mandibular cast (Fig. 47.4). The interim splint will facilitate accurate antero-posterior and transverse positioning of the maxilla, since the recommended treatment sequence is to first perform the maxillary surgery. If the patient has an intact, stable dentition prior to surgery, it is unlikely that a final surgical splint will be necessary because the patient can be placed in a stable, reproducible occlusion following performance of the maxillary and mandibular osteotomies.

Surgical treatment

Anesthetic and medical management considerations

It is recommended that the surgeon and attending anesthesiologist discuss management of the airway, anesthetic techniques, and medical management of the patient prior to surgery to minimize the chance of perioperative complications.^{54–58} Fiberoptic nasopharyngeal intubation (possibly awake) with a RAE tube provides a secure airway and ample access to the surgical field. A tracheostomy is not routinely indicated to secure the airway, but is recommended where there is concern about the ability to safely perform nasopharyngeal intubation or where long-term postoperative airway management is required. Proper patient positioning and padding (e.g. gel pads) are important to reduce the risk of pressure ischemia, which may be increased due to size (BMI) of the patient, use of hypotensive anesthesia, and length of the procedure. Judicious intravenous fluid administration and use of intraoperative corticosteroids are helpful to diminish postoperative facial and parapharyngeal edema.

It is advantageous to use a modified hypotensive anesthetic technique during performance of the maxillary and mandibular osteotomies, to reduce blood loss, and to improve visualization of the surgical field.⁵⁹ The ability to achieve this level of reduction in blood pressure is dependent on the patient having a near normal blood pressure preoperatively and underscores the importance of adequately treating any hypertension that was identified at the consultation visit. In addition to hypertension, patients with OSA may have a history of ischemic heart disease, myocardial infarction, and possibly stroke, and in these individuals it is especially important to maintain adequate organ perfusion. Although it is uncommon that blood transfusion will be necessary intraoperatively, the patient is presented the option of donating 2 units of autologous blood, so blood will be available if needed.

Surgical technique and sequencing of care

The recommended sequencing of surgical care is as follows: (1) application of maxillary and mandibular arch bars; (2) total Le Fort I maxillary osteotomy; (3) bilateral sagittal split ramus osteotomies of the mandible; and (4) genial advancement if indicated.

A Le Fort I total maxillary osteotomy is performed using standard techniques with a modified step design (Fig. 47.5). The purpose of the step modification of the maxillary lateral wall osteotomies, is to facilitate bony interfacing and presumably enhance the stability of the maxillary advancement. After completion of the osteotomy, the maxilla is mobilized until it can be passively positioned forward to the planned surgical position, as verified with the interim splint. To facilitate complete mobilization, slow, deliberate “controlled force” is used, usually in conjunction with a Rowe forceps. Force is modified accordingly, to maintain adequate perfusion to the maxilla. Adequacy of perfusion of the maxillary soft tissues is visually monitored during the mobilization. The interim splint is then placed between the maxilla and mandible and the complex is wired into maxillomandibular fixation (MMF). The complex is then passively rotated superiorly to the proper vertical position, as confirmed by measurement to an external reference pin. The piriform rim is recontoured and the anterior nasal spine is reduced (Fig. 47.1) to minimize overprojection and widening of the nasolabial soft tissues, that may occur as a result of the large advancement of the maxilla.

The maxilla is then fixated by placement of 2.0 mm L-shaped bone plates at the piriform rim and

Fig. 47.5 Total LeFort I maxillary osteotomy with modified step design of lateral wall (a), placement of maxillary bone plates at piriform rim and zygomaticomaxillary buttress (b), reduction of anterior nasal spine and recontouring of piriform rims (c), and placement of mono-cortical bone plate fixation of the mandible, to minimize risk of injuring the inferior alveolar nerve (d). (From Boyd SB. Management of obstructive sleep apnea by maxillomandibular advancement. *Oral Maxillofac Surg Clin North Am* 2009; 452, with permission.)

zygomaticomaxillary buttress regions bilaterally (Fig. 47.5). The configuration of these plates produces a buttressing effect, which should enhance the stability of the large maxillary advancement together with adequate bone interfacing and good immediate stability of the maxilla. Using this technique, the author has observed very good long-term stability of the maxilla and has not found it necessary to place any bone grafts. The potential benefits of not having to perform a bone graft include: decreased operative time, elimination of any donor site morbidity, and earlier patient ambulation after surgery.

Following confirmation that the maxilla is in the proper anatomic position (as verified by the interim splint), the maxillary soft tissue wound is then closed. An alar base cinch suture (3/0 non-resorbable suture) is placed to reapproximate the alar bases at the preoperative position. A V-Y closure of the upper lip (at the midline) is then completed. These two techniques are designed to maintain proper anatomic position of the nasolabial tissues.⁶⁰

Bilateral sagittal split ramus osteotomies (BSSRO) of the mandible are then completed using standard techniques. The mandible is split using a slow deliberate method of controlled force to facilitate visualization of the inferior alveolar nerve and diminish the chance of injury to the nerve. Minimizing surgical trauma to the inferior alveolar nerve is especially important, since OSA patients are generally middle-aged and presumably have a decreased ability to recover from a nerve injury. Once the split is completed, care is taken to maintain soft tissue attachments so the entire hard tissue–soft tissue complex is advanced, for the purpose of increasing the posterior airway space. The mandibular osteotomies are then stabilized in the advanced position by either bone plates and monocortical screws or three bicortical screws (Figs 47.1, 47.5).

A genial advancement is not routinely performed, but if indicated will be performed following completion of the Le Fort I and BSSRO. A variety of methods has been used for genial advancement, ranging from a standard genioplasty to a more isolated genial tubercle advancement. The main objective of the procedure is to advance the genioglossal musculature for the purpose of advancing the tongue and presumably increasing the posterior airway space.

Postoperative care and monitoring

Once the surgical procedure has been completed and the patient is sufficiently awake to meet criteria for extubation, the nasopharyngeal tube is typically removed in the operating room. This protocol has the advantage of having both the treating anesthesiologist and surgeon present at the time of extubation, as well as all necessary equipment immediately available if reintubation is necessary. Using this protocol, it is very uncommon for a patient to require reintubation. After extubation and stabilization, the patient is

transported to the ICU for overnight monitoring. The patient's airway and associated medical conditions will need to be closely monitored. The patient is closely observed for any apneic events and oxygen supplementation is administered by face mask to maintain adequate oxygen saturation. Using this protocol, few apneic episodes are generally observed and adequate oxygen saturations can be maintained, so postoperative CPAP has not routinely been used.

It is not uncommon to observe postoperative hypertension and appropriate antihypertensive agents should be used to keep the patient at a normotensive state. For patients with pre-existing hypertension, or any other significant medical conditions, it is beneficial to develop a plan preoperatively, in conjunction with the patient's physician (cardiologist or primary care physician), for medical/pharmacological control of postoperative blood pressure. For the first postoperative night, pain is controlled through the use of incremental intravenous dosing of narcotic analgesics. Close observation of the airway occurs during administration of the analgesics as respiratory depression may occur at even low doses of narcotics in OSA patients.

Typically the patient will be stable enough to be transferred to a step-down unit on the first postoperative day. Pain control can be maintained by a patient-controlled anesthesia (PCA) pump or liquid medications administered orally. Normal postoperative recovery will be initiated including ambulation and consumption of a liquid diet, similar to a typical orthognathic surgery patient. It is recommended that night time oxygen saturations be monitored by pulse oximetry until the patient can maintain near normal oxygen saturations on room air while sleeping.

The typical hospital stay is 2–3 days. The patient will then be evaluated on an outpatient basis every 1–2 weeks for about 6–8 weeks following surgery. During these visits, wound healing, neurosensory function, skeletal stability, occlusion, range of mandibular mobility, and TMJ function will be assessed, and the patient will be instructed in wound care and rehabilitation of masticatory function. When healing is complete and the patient has regained normal jaw function, the arch bars will be removed under sedation and local anesthesia, in an outpatient clinic setting. A nocturnal polysomnography study, cephalometric radiograph, and photographs should be completed about 3–6 months following surgery to objectively evaluate treatment outcome (Fig. 47.6).

Pediatric considerations

For children, there are important special considerations in the evaluation, treatment planning, and surgical techniques that are different from the typical adult with OSA. During the initial consultation visit, it is important to obtain a comprehensive medical history. In the pediatric population, several congenital craniofacial syndromes are associated with OSA.

Fig. 47.6 Frontal facial (a), lateral facial (b), lateral cephalometric radiograph (c), and intraoral (d–f) images of patient shown in Fig. 47.2, at long-term evaluation 8 years following MMA. The patient had total resolution of OSA (long term post-MMA AHI = 0.2), increased posterior airway space, improvement in facial profile and maintenance of normal dental relations. Clinical examination showed normal sensation of the inferior alveolar nerves, normal range of mandibular mobility (60 mm) and normal temporomandibular function. The Epworth Sleepiness Scale showed no significant sleepiness (ESS = 4), and the SAQLI disease specific quality of life survey demonstrated a high positive effect of MMA and no significant treatment-related symptoms.

These syndromes include: Pierre-Robin sequence, Treacher Collins syndrome, hemifacial microsomia, and Nager's syndrome. Micrognathia is a common finding in many of these syndromes. Mandibular elongation by mandibular distraction osteogenesis (DO) has been shown to effectively treat micrognathia and concomitant OSA in children.⁶¹

Due to the underlying significant anatomic abnormalities in the craniofacial skeleton and upper airway in the young child with OSA, it is very beneficial to obtain CT imaging with 3D reconstructions for evaluation and surgical treatment planning. During the course of mandibular distraction, an interval 3D CT scan can be performed, to assess the magnitude and 3D characteristics of the distraction, and the concomitant changes in the upper airway.

The most common mandibular DO surgical technique includes bilateral mandibular distraction osteogenesis using an angle oblique osteotomy design.⁶¹ Following performance of the osteotomies, bilateral or multidirectional distracters are placed extraorally. Typically the distraction protocol includes a 3–7-day latency period followed by distraction at a rate of about 1.0 mm per day. A consolidation period of about 6–8 weeks occurs after completion of the mandibular distraction.

A recent meta-analysis showed that mandibular DO prevented the need for tracheostomy in 91.3% of neonates or infants and 97% of children showed resolution or improvement in their OSA symptoms.⁶¹

Chapter 48

Distraction Osteogenesis

Lim K. Cheung, Hannah Daile P. Chua, Firdaus Hariri, John Lo,
Andrew Ow, and Li-wu Zheng

This chapter provides a comprehensive overview of the background history and development of distraction osteogenesis, along with a discussion of its possible practical applications in the future. The different methods of distraction, extraoral and intraoral, are described in detail, and the biological process of the distraction procedure is explained. The advantages of distraction are discussed, including: (1) no requirement for bone graft; (2) simultaneous expansion of surrounding soft tissue; (3) it is possible to repeat the surgery; (4) it is a simple technique with minimal blood loss. The wide use of the method in craniofacial cases and intraoral alveolar bone distraction is clarified.

Introduction

Distraction osteogenesis is a clinical tissue engineering method of regenerating new bone by gradual stretching of divided bone segments with the use of a mechanical device. It has been called osteodistraction, callotasis, callus distraction, and bone lengthening in the literature. This technique has generated enormous interest among oral and maxillofacial surgeons because of the possibility of treating severe craniofacial deformities beyond the clinical limits of conventional orthognathic surgery. In contrast to the conventional orthognathic surgical techniques, distraction offers a few advantages including: (1) there is no requirement for bone grafts and hence no donor site morbidity; (2) it allows simultaneous expansion of the surrounding soft tissues; (3) it is feasible to repeat the distraction or surgery on the same site after distraction; and

(4) it is a simple technique with minimal blood loss that can be applied to children and infants.

History and development

This technique was initiated by surgeons in the late 1880s, and Codivilla of Bologna, Italy was the first to publish a case report in 1905.¹ He applied external traction following an elective osteotomy of the femur by hanging a weight at the end of the bed. In 1921, Putti² designed a unilateral device for femoral lengthening. He made use of large half-pins and an external telescoping tube with a compressed external spring. In 1927, Abbot³ modified the method and this became the accepted technique in distraction of long bones. He utilized a step osteotomy in conjunction with through and through pins attached to a frame on both

sides of the limb. The limb was slowly lengthened via a compressed spring in an external device. Due to a high complication rate of non-union and fibrous union, the technique gradually became obsolete.

It was not until 1954 that Dr Gavriel O. Ilizarov, a Russian orthopedic surgeon, revitalized the technique by researching on distraction osteogenesis for correction of post-traumatic deformities of the lower extremities.⁴ After World War II, a lot of Russian veterans were sent to Siberia for rehabilitation and management of problems such as osteomyelitis and malunion from war injuries experienced during the war. Dr Ilizarov developed a ring-shaped external fixator utilizing Kirschner wires, later called the “Ilizarov ring”. He used this device to treat patients with the technique of tension-wire external skeletal fixation. He admitted in his book that one of the patients wearing the Ilizarov ring turned the screws for uprighting the malaligned segment in the reverse direction and this resulted in lengthening of the leg without any complication. This accidental discovery of the possibility of achieving limb lengthening with his devices paved the way for developing many distractors achieving lengthening of different long bones. During the next 30 years, Ilizarov perfected this clinical technique of distraction bone lengthening osteogenesis.⁵⁻⁸ Through clinical experience and extensive animal experiments, he defined the factors contributing to consistent success by using a corticotomy with preservation of the periosteal and medullary blood supply to the bones, and bone expansion in small increments of 1mm per day in four rhythms. The Ilizarov technique started to become popular initially in Russia and later worldwide, particularly after Dr Ilizarov lectured on his successful experience at a surgical symposium in New York in 1988.

Development of distraction applications on cranio-maxillofacial skeleton

The feasibility of achieving distraction osteogenesis in intramembranous bones, such as the cranio-maxillofacial region, was first reported in 1972, when Snyder used a Swanson external fixation device to lengthen a canine mandible. In his experiment, Snyder surgically removed a 1.5cm segment of one side of the mandible.⁹ The bone was allowed to heal and a severe crossbite developed. This was corrected 10 weeks later by performing an osteotomy, applying an external fixator and gradually relengthening the mandible. After 14 days, the original occlusal relationship was restored. In 1976, Michieli and Miotti modified Snyder’s work by using an intraoral device and achieved similar success.¹⁰ In 1984, Kutseviak and Sukachev took the experiment further by lengthening a normal canine mandible 1.2cm using the Ilizarov principle.¹¹ These studies prompted Karp *et al.*^{12,13} at New York University to perform a detailed

histological analysis of the ossification process following mandibular distraction in a canine model, in order to confirm the stages of distraction healing in intramembranous bones; these bones are different embryonically from the long bones that ossify by endochondral ossification. This laboratory work eventually paved the way for the first four cases of human mandibular distraction published by McCarthy in 1992.^{14,15} The results of these studies were of great clinical significance because they proved that mandibular distraction can be achieved successfully with minimal risk of complications.

Biological process of distraction osteogenesis

Distraction osteogenesis consists of five sequential stages: osteotomy, latency, active distraction, consolidation, and remodeling. The inflammation and granulation tissue formation at the initial stages of distraction osteogenesis are similar to fracture healing until they are interrupted by traction forces. The collagen tissues are stretched when a traction force is applied to the bone segments. This traction force generates tension in the tissues that connect the bone segments, which stimulates new bone formation parallel to the vector of distraction.¹⁶

Osteotomy is the surgical separation of a bone piece into two segments. Discontinuity of a skeletal segment results in bleeding and formation of a blood clot. This triggers a biological process of bone repair known as fracture healing. This process involves recruitment of osteoprogenitor cells, followed by cellular modulation or osteoinduction, and establishment of an environmental template (osteoconduction). As a result, a reparative callus is formed within and around the ends of the fractured bone segments.

Latency is the period from osteotomy to the onset of active distraction. It represents the period allowing the reparative callus formation. The sequence of events occurring during the latency period is similar to that seen during fracture healing. Following the surgical separation of a bone into two segments, a cascade of events takes place.

Initially, as a result of bony disruption and fixation with a distractor, a hematoma forms between and around the bone segments. The hematoma is converted to a clot followed by an ingrowth of vasoformative elements and capillaries for the restoration of blood supply. The clot is replaced with granulation tissue consisting of inflammatory cells, fibroblasts, collagen, and invading capillaries (Fig. 48.1a).

Inflammation is followed by the soft callus stage, which is marked by a continuous ingrowth of capillaries into the callus. A minicellular network of growing capillary loops is formed in the medullary canal of both proximal and distal segments in the areas adjacent to the osteotomy line. Less differentiated, free circulating osteogenic cells are located inside the

Fig. 48.1 The biological sequence of bone regeneration in distraction osteogenesis. (a) Hematoma is replaced by granulation tissue in latency period. (b) Progressive enlargement of gap during active distraction. (c) Osteogenesis with fine trabeculae at margin of distraction gap. (d) Extension of osteogenesis to the center of the gap in consolidation period. (e) Maturation of distraction regenerate in late consolidation period. (f) Remodeling of bone and re-establishment of inferior alveolar canal.

terminals of the newly formed capillaries. During the soft callus stage, granulation tissue is converted to fibrous tissue by fibroblasts. Cartilage also replaces the granulation tissue.

Active distraction is the period characterized by movement of the osteotomized bone segments by a mechanical distractor. Bone segments are gradually pulled apart, resulting in formation of new bony tissues within the progressively increasing intersegmentary gap (Fig. 48.1b).

The growth-stimulating effect of tension activates a cascade of biologic elements. This includes prolongation of angiogenesis with increased tissue oxygenation, and increased fibroblast proliferation with intensification of biosynthetic activities. Capillaries grow into the fibrous tissues, thereby extending the vascular network, not only toward the center of the gap but also toward the medullary canal of the adjacent bone segments. Capillary terminals actively invade the fibrous tissues, supplying them with

Fig. 48.2 The ossification pathways of distraction osteogenesis. (a) Distraction regenerate forms predominantly via membranous ossification (arrows) while endochondral ossification occurs occasionally in the peripheral and central area (frame). (b) At higher magnification of the frame in (a), a cartilage island is clearly seen. (c) Transchondroid bone formation. Focal region of chondrocytes (frame) surrounded by a mineralized matrix. (d) At higher magnification of the frame in (c), the cartilage cell foci are clearly visible.

mesenchymal cells that differentiate into fibroblasts, chondroblasts, or osteoblasts.

The osteoblasts, located among the collagen fibers, lay down osteoid tissue and eventually become enveloped as bone spicules, which gradually enlarge by circumferential apposition of collagen and osteoid. Primary trabeculae begin to form. Osteogenesis is initiated at the existing bone walls and progresses toward the center of the distraction gap (Fig. 48.1c).

Consolidation is the period between cessation of traction force and removal of the distraction device. It represents the time required for completing the mineralization of the distraction regenerate. After distraction ceases, the fibrous interzone gradually ossifies and one distinct zone of woven bone completely bridges the gap (Fig. 48.1d). As the regenerate matures, the zone of primary trabeculae significantly decreases and later is resorbed completely (Fig. 48.1e).

Remodeling is the period from the application of full functional loading to the complete remodeling of the newly formed bone. During this time, the initially formed bony scaffold is reinforced by parallel-fibered lamellar bone. The cortical bone and marrow cavity are restored. Remodeling of the Haversian system normalizes the bony structure into cortical and cancellous bone. Finally, the structure of newly formed

bony tissue is comparable to and indistinguishable from that of the pre-existing bone (Fig. 48.1f).

There are two basic modes of mineralization of the distraction regenerate. Endochondral ossification means bone mineralization is achieved via a cartilaginous intermediate. This is the mechanism responsible for bone mineralization in the long bone. Intramembranous ossification means direct bone mineralization without a cartilaginous intermediate and is a specific mechanism responsible for mineralization of cranio-maxillofacial bones. Distraction regenerate forms predominantly via intramembranous ossification (Fig. 48.2a), whereas endochondral ossification occurs occasionally in the periphery or any ischemic tissue areas. (Fig. 48.2b).⁷ Beside the two principal bone formation pathways, a third bone formation method, transchondroid bone formation, can occasionally be observed during the bone healing process of distraction osteogenesis.¹⁷ In this form of mineralization, focal regions of chondrocytes are surrounded by a mineralized matrix, and then directly transformed into bone rather than by the usual endochondral pathway (Fig. 48.2c). The matrix of this chondroid bone is more similar morphologically to bone than cartilage, but the cells are indistinguishable from chondrocytes (Fig. 48.2d). Factors resulting in low

oxygen tension within the distraction regenerate, such as unstable fixation and ischemia, may cause development of a cartilaginous intermediate during distraction osteogenesis.

Mandibular distraction

Indications for mandibular distraction osteogenesis

The initial application of mandibular distraction osteogenesis was mainly directed towards lengthening the ramus and body of the mandible in micrognathia secondary to congenital conditions such as hemifacial microsomia or Treacher Collins syndrome. It was also used in relieving airway distress in neonates suffering from congenital conditions such as Pierre Robin sequence. Its success in treating congenital deformities led to its application in adults where orthognathic surgery would traditionally have been used. These included cases of developmental class II mandibular hypoplasia and patients with obstructive sleep apnea (OSA). Mandibular distraction osteogenesis has also been used to treat transverse mandibular width discrepancy, temporomandibular joint (TMJ) ankylosis (by transport distraction), and moderate to severe alveolar ridge deficiency (by alveolar widening or increase in height). The common indications for mandibular distraction osteogenesis are listed in Table 48.1.

The current applications of distraction osteogenesis for the mandible include: lengthening of the mandibular body and ramus, transverse expansion of the symphysis, and bone transport for reconstruction of the mandibular body or condyle. The development of mandibular distraction has been largely guided by the capability of the new distractor designs. A large array of devices for different applications is commercially

available. The mandibular distractors can be broadly categorized into two main groups – extraoral and intraoral. Extraoral distractors are attached to the mandible via percutaneous pins and connected to the distractor outside the skin, whereas intraoral distractors are concealed inside the oral cavity. In some designs, the activation rod of the intraoral distractors exits through the skin to allow more convenient activation.

Extraoral mandibular distraction

Extraoral distraction osteogenesis evolved from the mini orthopedic devices used for limb lengthening. The early development of craniofacial distractors started with linear bone movement. With the initial success in clinical applications for mandibular body lengthening, the development shifted to achieve two- or three-dimensional mandibular distraction. The benefits of the new distraction devices are their capability in achieving: (1) angular adjustment to attain bi-directional bone lengthening; and (2) multiplanar bone movement, particularly in lateral facial expansion. Recently, modifications include: the use of titanium metal to reduce the weight of the distractor, which is particularly important for infants; and a composite design of titanium and bioresorbable polymer for the fixation plates and screws.

Extraoral distraction by orthopedic devices

In 1992, McCarthy used the Hoffman Mini Lengthener (Stryker Leibinger, Kalamazoo, MI, USA) to distract the mandibles in four children who presented with craniofacial anomalies.¹⁵ The appliance was initially designed for hand reconstruction, and was attached to the osteotomized bone segments with two pairs of pins. In his series, a maximum lengthening of 24 mm was achieved. With the integration of postsurgical orthodontics, good long-term results were obtained. Using a similar device, Klein and Howaldt were also able to achieve satisfactory results in 1995 in nine patients with mandibular hypoplasia.¹⁸

In 1993, Perrott and co-workers used another lengthening device (Synthes, Paoli, PA, USA) to perform mandibular widening and soft tissue expansion in a patient with hypoglossia–hypodactylia syndrome.¹⁹ This distractor was a mini orthopedic device for leg lengthening, which consisted of two double-pin clamps connected to a linear telescopic distractor. A symmetrical 10 mm mandibular lengthening with expansion of the overlying soft tissue was achieved over 30 days.

The first multiplanar mandibular distraction was reported by Pensler *et al.* in six patients using an Orthofix Mini Fixator (Orthofix, Inc., Richardson, TX, USA) in 1995.²⁰ This device was based on a system designed for reduction and fixation of long bone fractures. The distractor was composed of a sliding double-pin clamp attached to an activation rod and

a rotating double-pin clamp connected to the distractor by a ball-and-socket joint, which facilitated multiplanar distraction as required by the patients' deformities. The activation was at a rate of 0.25 mm four times a day. The average bone lengthening was 18.3 mm. All patients showed marked improvement in oral functions including the occlusion, airway, and esthetics.

It is noteworthy that all the devices described above were evolved from the available orthopedic rigid fixation systems. Despite the ability to resist mandibular segment displacement from mastication or muscle tension, high precision is required for positioning of the devices to avoid any undesirable bony movement during activation. The distractors are considered by most maxillofacial surgeons to be bulky and are limited mainly to mandibular body lengthening.

Extraoral distraction by mandibular distractors

Klein and Bitter¹⁸ introduced their own design of extraoral device for mandibular lengthening modified from the Hoffman Mini Lengthener. This Unidirectional Mandibular Distractor (Normed Medizin-Technik GmbH, Tuttlingen, Germany) was composed of a geared device connected to a rotating clamp and a sliding clamp for better adaptation to the mandible. Each clamp holds a pair of transcutaneous osseous pins for fixation (Fig. 48.3a).

In 1996, Molina and Ortiz-Monasterio reported their technique and distractor, modified from McCarthy's experience.²¹ Their technique used an oblique buccal corticotomy on the lateral cortex of the mandible from the gonial angle to the retromolar region. They modified the traditional distractor design to a semi-rigid fixation system. The Molina Unidirectional Distractor (KLS Martin Group, Tuttlingen, Germany) was composed of one intraosseous stainless steel pin inserted on either side of the corticotomy segments (Fig. 48.3b). The pins were connected to the distractor, which was composed of two pin-holding plates joined by an activation screw capable of linear elongation. There are three patterns available for different age groups and maximal distraction lengths for each age group are recommended: infant (28 mm), children (43 mm), and adults (53 mm). A 5-day latency period was recommended before activation of the device at a rate of 1 mm per day. The pins, which were parallel during the insertion, were expected to become divergent as the distractor was activated because the activation rod was made of softer stainless steel that would be bent in response to pressure. According to Molina, the curvature of the distraction rod would enhance the remodeling of the underlying bone, resulting in a curvilinear elongation of the mandible at the angle region. The progressive divergence of distractor produces more elongation of the structures located laterally rather than medially, and hence results in transverse improvement of the facial con-

tour, which is of particular benefit for correction of hemifacial microsomia.

Molina and Ortiz-Monasterio also introduced the use of their Bi-directional Distractor (KLS Martin Group, Tuttlingen, Germany) in patients with deformities involving both the mandibular body and ramus (Fig. 48.3c). Two lateral corticotomies were made, one in front of and one at the gonial angle to allow distraction in the horizontal and vertical planes respectively. The distractor was connected by three transosseous pins. The central pin was fixed to the mandibular segment in between the two corticotomies to act as a fixed pivot for independent vertical and horizontal distraction. The other two pins were fixed to the body and ramus respectively for attachment to the activation rods. There are two sizes available, allowing a maximum of either 56 mm or 76 mm lengthening. From their case series of 106 patients receiving either uni-directional or bi-directional distraction, good esthetic and functional results were achieved with no report of skeletal relapse.²¹

Further modifications of the bi-directional devices provided angular adjustment between the body and ramus distraction vectors during activation. One example is the Bi-directional Mandibular Distractor (Normed Medizin-Technik GmbH, Tuttlingen, Germany), which is composed of a middle joint piece, from which two geared distraction rods extend in different directions (Fig. 48.3d). This design enables independent control of the vertical and horizontal components of distraction. In addition, a more controllable position of the mandibular angle is achievable. Klein and Howaldt reported their experience with this device in 18 patients with various degrees of mandibular hypoplasia.²² The amount of bone lengthening ranged from 7–45 mm horizontally and 7–50 mm vertically.

In complex craniofacial deformities, such as Purzanky type IIb or III hemifacial microsomia, the mandibular deformities can involve horizontal, vertical, and transverse planes. A three-dimensional (3D) surgical correction is therefore necessary to restore the facial symmetry. To achieve an independent lengthening of the mandibular body and ramus combined with gradual angular correction in the situation described above, a multiplanar distraction device is essential to achieve 3D correction. The Multi-directional Mandibular Distractor (Normed Medizin-Technik GmbH, Tuttlingen, Germany) is a pioneering European-designed model modified from the earlier bi-directional version (Fig. 48.3e). This 3D device is composed of two geared distraction rods with one free movable rider. Both rods are connected in the middle by a special joint with attachments to two additional intraosseous pins, which allow independent callus lengthening. The central piece has two universal joint mechanisms allowing each rod to have independent 3D vector control.

The Multi-Guide Mandibular Distraction Device (Stryker Leibinger, Kalamazoo, MI, USA) was an

(e) Multi-directional Mandibular Distractor (Normed). (f) Multi-Guide II Mandibular Distraction Device (Stryker Leibinger). (g) External Multi Vector Distractor (Synthes). (h) 3D Xternal Distraction System (KLS Martin).

American-designed multi-planar distraction device introduced by McCarthy in 1998. This device was made of stainless steel and consisted of two activation rods with sliding clamps connected in the middle by a universal hinge. Each activation rod could achieve linear bone lengthening of 15 mm. There were two additional activation screws for independent centers of rotation of the distracted callus in vertical and transverse plane of up to 90°. As a result, bone regeneration could be manipulated three-dimensionally during the activation process.^{23,24} In order to improve the dimensions of activation, the Multi-Guide II Mandibular Distraction Device

(Stryker Leibinger, Kalamazoo, MI, USA) was marketed in 2000 by extending the activation rods to 20 mm and 35 mm (Fig. 48.3f).

Despite the superior ability in callus adjustment during activation, it is obvious that all the multiplanar distractors share the same limitation as the uni- and bi-directional distractors: a significant increase in weight and size, which may cause symptoms such as discomfort or neck pain during activation and consolidation periods. As a result, all the recent models have switched to a lighter-weight model made of titanium and interchangeable parts for customization.

The Multi Vector Mandible Distractor (Synthes Maxillofacial, Paoli, PA, USA) is a titanium self-assembly of two distraction arms attached to a 3D hinge for multiplanar movement (Fig. 48.3g). Fixation is achieved by four transosseous pins connected to the distractor arms by a pair of holding clamps. The distractor arms are available in different lengths, ranging from 15–85 mm. Angular adjustment could be achieved up to 90° in either direction, and transverse adjustment is feasible up to 32° towards and 16° away from a patient. Through different combinations of assemblies, the distractor can be customized to any individual's need, and it can be transformed from a single vector device for linear bone lengthening, to a multivector device of achieving 3D manipulation of the distracted callus. In combination with a reconstruction plate, this device could be transformed for the purpose of bone transport in reconstruction of segmental mandibular defects. Lastly, a consolidation rod made of ultra light-weight carbon fiber is available for replacement of the distractor. Altogether these modifications enable more precise control of the three vectors and enhancement of patient comfort.

The 3D Xternal Distraction System (KLS Martin Group, Tuttlingen, Germany) is a newly introduced product to provide gradual multidirectional lengthening and stabilization of bone segments (Fig. 48.3h). This light-weight titanium, low-profile device is an assembly of interchangeable distraction rods, allowing a maximum of 85 mm lengthening, and a 3D hinge for vertical and transverse vector adjustment. It allows vertical angular adjustment from -6° to +98°, and transverse angular adjustment of 20° in either direction. The device can be customized to perform bone transport, and a carbon fiber rod is also available to replace the bulky distractor body.

Intraoral mandibular distraction

The pioneer models for intraoral mandibular distraction were based on modifications of the available orthodontic expansion appliances, and miniaturization of extraoral distractors.²⁵ Based on the principles of the palatal expander developed by Bell and Epker,²⁶ Guerrero published a report of the first intraoral tooth-borne appliance for distraction of the mandibular symphysis in 1991.^{27,28} The device is a custom-made orthodontic Hyrax appliance for transverse widening. In 1994, McCarthy and co-workers developed a bone-borne device for intraoral distraction of the mandibular body.²⁹ The Uniguide Mandibular Distraction Device (Stryker Leibinger, Kalamazoo, MI, USA) is indeed a miniaturized version of their external model, which consisted of two clamps attached to the bone via pairs of pins connected by a telescopic distraction rod. At about the same time, Wangerin and Gropp developed an Intraoral Titanium Mandibular Distraction Device (Medicon eG, Tuttlingen, Germany), which was the first distractor

using miniplates rather than intraosseous pins for fixation.

The introduction of intraoral devices greatly improved patients' acceptance of mandibular distraction. Despite the ability to hide the devices inside tissues and the absence of facial scars, there are limitations to the development of the intraoral distractors due to miniaturization of the devices and restricted mouth opening in some patients. Further development of intraoral distractors has evolved along three main routes: (1) designs based on the anatomical location; (2) designs for universal adaptation on any part of the mandible; and (3) custom-made distractors.

Anatomically, a mandible is composed of two halves that are fused at the midline forming a symphyseal curve. Each mandibular half is made up of a horizontal body and a vertical ramus, forming the gonial angle. Articulation to the cranium is by the condyle located on the posterior upper end of the ramus. Mandibular intraoral distractors have been designed based on these anatomical characteristics and are further elaborated as described below.

Mandibular ramus distraction

In mandibular ramus distraction, the vector of bone lengthening is usually vertical. It is commonly indicated in patients with short mandibular ramus such as hemifacial microsomia. Owing to the limited access, the activators will be either exposed intraorally using a double hinge joint, or transcutaneously at the submandibular or the retromandibular region.

Wangerin and Gropp developed a Vertical Mandibular Distraction Device (Medicon eG, Tuttlingen, Germany)³⁰ for intraoral lengthening of the ascending ramus in 1996. This device was made of titanium and consisted of a rectangular distraction cylinder with two T-shaped miniplates. To facilitate the activation, a gear was added to the distraction cylinder, which was then connected by a universal joint to the activation pin perpendicular to the distractor body. There were two different sizes of this distractor body available to enable a maximum vertical elongation of 15 mm and 20 mm, respectively.

Diner and Vazquez introduced an intraoral distraction system (Stryker Leibinger, Kalamazoo, MI, USA) for uni-directional ramus lengthening in 1997.³¹ This device was a self-assembly of different combinations of distractor frames and rods. The distractor frame included a rectangular framework, and two fixation clamps were secured to the bone with transosseous pins (Fig. 48.4a). The frames were available in two sizes allowing 18 mm and 28 mm bone lengthening, respectively. The clamps were connected to each other with two sliding rods for stabilization of rotational forces. The distraction rod consisted of a threaded portion and a smooth portion connected to each other by a double hinge. The rods were available in different lengths ranging from 85–125 mm to meet

Fig. 48.4 Examples of intraoral mandibular ramus distractors. (a) Uni-directional Distraction System (Stryker Leibinger). (b) Bi-directional Distraction System (Stryker Leibinger). (g) Logic Mandibular Distractor (Osteomed).

the requirements of different age groups and sizes of the oral cavity while maintaining the rod exposed above the mucosa, but inside the oral cavity. From their report on nine young patients, the amount of ramus elongation achieved ranged from 12–28 mm. In a latter modification, a bi-directional device was introduced (Fig. 48.4b). This model was composed of a distractor frame fitting to two detachable rods in order to perform angulation adjustment of 50° and independent bone lengthening of both the mandibular ramus and body basing on a single osteotomy at the gonial angle. The maximum bone lengthening, 20 mm, was considered insufficient for most mandib-

ular ramus lengthening. Although the two rods are color coded, patients can find them confusing and mistakes in distraction of the wrong rod can occur.

In 1998, Hoffmeister introduced a low-profile intraoral distractor – the ascending Mandibular Ramus Distractor (KLS Martin, LP, Jacksonville, FL, USA).³² This device is composed of a threaded unidirectional distraction rod (15–25 mm) and two Y-shaped micro-osteosynthesis plates. The activation is achieved by rotating a double hinge activator, which allows better location relative to the mandibular ramus. In addition, the activator rod could be shortened after activation to improve patient comfort (Fig. 48.4c).

At about the same time, Sailer introduced the Zurich Pediatric Ramus Distractor (KLS Martin, LP, Jacksonville, FL, USA) for uni-directional lengthening of the mandibular body and ascending ramus. This is a miniaturized device composed of a cylindrical body enclosing a threaded distraction rod with two osteosynthesis plates attached. The plates are relatively shorter than in Hoffmeister's design, and are available in the form of cloverleaf or Y-shaped. Owing to the shorter length of connection between the plate and body, fixation of the plate can be located on the anterior ramus or turned around the fixation plate at the retromolar region. There are three maximal distraction lengths available: 15 mm, 20 mm, and 25 mm. Activation is via a semi-flexible rod that can be bent for a curvilinear placement inside the labial sulcus without causing ulceration of the labial mucosa (Fig. 48.4d).

The Wood Zurich Intraoral Distractor (KLS Martin, LP, Jacksonville, FL, USA) is a modified design introduced by the same manufacturer for bi-directional distraction. This distractor is composed of two cylinders containing a threaded distraction rod (Fig. 48.4e). One contourable mesh can be attached to each cylinder, and they are joined by a fixed curvilinear rod. There are two activators for lengthening the mandibular body and ramus up to 20 mm.

The Synthes Mandible Distractor (Synthes Maxillofacial, Paoli, PA, USA) is a single vector distractor designed mainly for ramus elongation (Fig. 48.4f). It is composed of two miniplates attached to a telescopic distraction rod. The stainless steel distraction body is enclosed inside a sleeve to minimize possible soft tissue entrapment. The distractor comes in only one length allowing up to 30 mm of distraction. There are left and right models available based on the foot plate configuration to facilitate anterior or posterior positioning of the screws. Owing to the considerable length and the lack of any hinge or flexible component, the distractor placement is usually semiburied with the activator exposed externally at the submandibular region. As well as vertical ramus elongation for correction of a short ramus, this distractor has been successfully used for transport distraction in condylar reconstruction.³³ In the second-generation device, the distractor has been modified to be a titanium ramus device with a detachable upper titanium plate to enhance distractor removal with the possibility of leaving the plate behind fixed to the mandibular ramus.

The Logic Mandibular Distractor (Osteomed, Dallas, Texas, USA) was developed based on the principle of the logarithmic properties of mandibular growth (Fig. 48.4g).^{34,35} In this low-profile device, the distraction rod is curved to allow a fixed curvilinear trajectory that mimics the natural growth curve of the mandible. There are three types of device available in this distraction system, which allows mandibular lengthening from 24–52 mm. Fixation is by self-tapping screws and activation is via a flexible wire that

provides access through the oral mucosa for ease of activation. During consolidation, the activation wire can be cut to facilitate submersion of the distractor which reduces patient inconvenience.

In 2004, Schendel illustrated the application of a Logic distractor in a case of hemifacial microsomia.³⁶ In this case, the ramus osteotomies were achieved by bilateral sagittal splits, which permitted immediate bone lengthening and correction of any bone misalignment if a counterclockwise rotation of mandible were indicated to correct open bite. The use of a curved distractor enables a logarithmic path of activation, which can create a more normal mandibular plane angle and movement as well as minimizing possible development of anterior open bite after distraction. In addition, detachment of the activation rod allows the body to be submerged to enhance patient comfort. The Logic JR Pediatric Distraction System has subsequently been introduced for use in children and infants in whom poor compliance would be expected during intraoral activation. This distractor design is similar to the adult version except activation is through a detachable flexible cable exposed at the postramal region.

Mandibular body distraction

Mandibular body distraction is usually indicated for advancement of a retruded mandible. Generally speaking, the design of any mandibular body distractor is similar to the corresponding ramus distractor, and activation is usually via an intraoral route. In infants and young children, surgeons prefer to place the activation rod exiting at the upper cervical region for active distraction due to lack of cooperation and the high mucosal infection rate around the activation rod.

Following the successful application in mandibular widening, Guerrero and Bell designed the DynaForm Intraoral Distractor (Stryker Leibinger, Kalamazoo, MI, USA), which is a universally applicable device for mandibular distraction (Fig. 48.5a). The device consists of a body with a distraction screw and four flexible arms. The distractor body is available in different lengths ranging from 7 mm up to 30 mm. Fixation is achieved by bone-borne, tooth-borne, or hybrid using either fork-end or screw-end terminals, which accept 2 mm screws or 0.024 inch stainless steel wires attaching to either the mandibular bone segment or teeth. The great flexibility of the distractor arms allows good intraoperative control of the distractor. This also minimizes the risk of inferior alveolar nerve damage from screw fixation. Using the fork-end terminals, distractor removal can be simplified just by cutting the arms and pulling the forked ends of the device out, leaving the fixation screws in the bone.

Apart from mandibular body lengthening and expansion, this distractor has also been used for intraoral bone transport combined with a reconstruction

plate in mandibular reconstruction.^{37,38} Despite the linear nature of regenerated bone from transport distraction, Guerrero reported the use of a two-phase transport disc distraction for reconstruction of the anterior mandible simulating the regeneration of a natural curvature.³⁹

In 1995, Cohen introduced a system of miniature distractors that can be universally applicable for the craniofacial skeleton, including the mandible. The Modular Internal Distraction System (Stryker Leibinger, Kalamazoo, MI, USA) is an assembly of two mini Wurzburg 3-D Mesh plates and a universal distractor body. The distractor body is available in two sizes allowing a maximum lengthening of 15 mm and 30 mm, respectively. The body is attached to a flexible activation cable, which can be bent to minimize postoperative irritation of the surrounding mucosa from intraoral activation. The cable can alternatively be exposed at less conspicuous sites, such as the sub- or postmandibular regions for extraoral activation. Owing to the highly contourable 3D mesh plates and the flexible activator, this distraction system can be easily adapted anywhere on the craniofacial complex as well.

In 1998, Razdolsky developed a series of tooth-borne and hybrid ROD distraction devices (Oral Osteodistraction, LP, Buffalo Grove, IL, USA), of which the anterior activated distraction mechanism can be attached to stainless steel crowns or miniplates by removable attachments.⁴⁰ In addition, he designed a special laboratory instrument allowing individually programmed fabrication of the distraction body along a predetermined axis of distraction based on individual occlusal records.

Following fixation of the stainless steel crown and/or plate, the distractor body is temporarily removed to enable the corticotomy cut to be made. Three types of distraction system are available for application in the mandible. The ROD-1 distractor is a completely tooth-borne appliance designed for interdental distraction in class I or class II malocclusion with crowding of the anterior teeth. The ROD-2 distractor is a hybrid device indicated for class II malocclusion with severe mandibular hypoplasia and minimal crowding of the anterior teeth. Fixation of the ROD-2 device is by miniplate and screws attached to the ascending ramus and through stainless steel crowns to the mandibular body. The ROD-3 distractor is a tooth-borne appliance designed for mandibular widening. In 1999, Dessner *et al.* reported the successful application of this distraction system for five patients with retrognathic mandible.⁴¹

Apart from the vertical distractor, Wangerin and Groppe also developed the Horizontal Mandibular Distractor (Medicon eG, Tuttlingen, Germany) for lengthening the mandibular body. This distractor is a modification of their original design (Fig. 48.5b), which is composed of a square-shaped cylinder (20–25 mm) with two miniplates (L- and T-shaped) on either end. From their 3-year report on 23 patients

undergoing both vertical and horizontal distraction, the amount of bone lengthening achieved was in the range of 7.5–25 mm.⁴²

Around the same time, Diner and Vazquez introduced another design of intraoral distractor (Stryker Leibinger, Kalamazoo, MI, USA) for uni-directional mandibular body lengthening. The design is almost identical to its ramus version, and is composed of an assembly of a distractor body and a distractor rod (Fig. 48.5c). There are two distractor bodies available for either 18 or 28 mm body lengthening. The difference to the ramus version is on the connection design of the activator, which is a single hinge joint. In a latter modification, it allows: (1) fixation by means of screws or titanium miniplate to adapt to the individual's anatomical variation; and (2) the distractor rod can be detached following activation to improve patient comfort. However, the activation length is relatively shortened (maximum: 23 mm). The bi-directional device was introduced a few years ago to increase the flexibility of the callus adjustment during activation, and hence further reduce the development of anterior open bite.

The Horizontal Distractor (KLS Martin, LP, Jacksonville, FL, USA) is a low-profile device designed by Hoffmeister. The device is generally similar to the ascending mandibular ramus distractor, and is composed of a threaded unidirectional rod and two Y-shaped micro-osteosynthesis plates (Fig. 48.5d). The difference from the ramus device is that the activator is a smooth rod of shorter length with a single hinge joining the threaded rod. The distractor is available in different length ranging from 10–20 mm. During fixation, the plates are adapted and fixed near the lower border of mandible. It is not uncommon for the distractor body to be exposed intraorally together with the activation rod.

Despite its name proposing indications for children and the mandibular ramus, the Zurich Pediatric Ramus Distractor (KLS Martin, LP, Jacksonville, FL, USA) can be applied for mandibular body lengthening in adults as well. Owing to the short connector length, the plate could be fixed to the upper part of the mandibular body instead of the lower, facilitating total submersion of the distractor body into the soft tissues. Despite the flexible activation rod, the rigid smooth rod connected to the distractor through a single hinge axis has also been introduced in latter modifications. Three designs are available to enable maximal bone lengthening ranging from 15–25 mm.

The Mandibular Distractor developed by Lorenz (W. Lorenz Surgical, Jacksonville, FL, USA), was designed solely for linear mandibular body lengthening. The device includes four miniplates connected to the distractor body of which one or two plates can be cut. The body is then attached to a flexible rod for activation (Fig. 48.5e). The distractor is available in different lengths from 5 mm up to 20 mm. It includes a special activation screw driver with an audible

“click” sound for clear determination of the amount of advancement. During the consolidation period, the flexible shaft can be detached to improve patient comfort. In addition, a resorbable distraction system was introduced. This design is composed of a metallic distraction screw joined with two resorbable plates (Fig. 48.5f). It is indicated in pediatric patients (less than 2 years old) with mandibular hypoplasia. There is only one surgical procedure and the removal of the distraction screw is a simple in-office procedure. The plates usually undergo spontaneous resorption within 1 year.

In 1998, Mommaerts introduced a horizontal distractor using the ascending ramus as anchorage.⁴³ His design was based on the concept that the ascending ramus provides: (1) a volume of bone that can receive large horizontal screws in the retromolar area, between the internal and external oblique lines; and (2) an area which is not prone to disuse resorption. The Mandibular Distraction – Dynamic Osteosynthesis System (Surgi-Tec NV, Brugge, Belgium) is composed of a single horizontal posterior fixation screw implant, a vertical hinge that copes with the lateral force vector in the condyles, a telescopic distraction module, and an anterior fixation unit that is fixed with monocortical screws (Fig. 48.5g). There are two distraction modules available to enable a maximum of 17 mm and 21 mm linear bone lengthening. From his initial clinical experience of 35 cases, Mommaerts cautioned that the placement of the distractor module and the posterior fixation screws should be close to the dental arch and away from any lateral occlusal interference and lower labial sulcus. In addition, the fixation screws should be long enough to avoid any slippage of the posterior fixation unit. From radiographic investigation using cephalometric radiographs, Hendrickx *et al.* noted the proximal segment was anteriorly rotated by about 3.3°, while the distal segment was posteriorly rotated after the lengthening procedure.⁴⁴ As a result, the angle of mandible was pushed back half the distance of the advancement of the anterior mandible.

In view of the broad age group indicated for distraction, it is difficult to define a particular size that fits all and this is the basis of the new modular design of mandibular distraction. Synthes and Medartis produced modular mandibular distractors at a similar time to enable surgeons to choose the most suitable components for individual cases (Fig. 48.5h). There is also improvement of the flexible activating rod design and it is easier to maintain hygiene around the mucosal exit. The latest improvement in rod design is the detachable rod design that enables the distractor to be buried inside the mucosal bed without the commonly infected distractor rod.

Significant esthetic and occlusal improvement can be achieved with mandibular distraction as illustrated in a clinical case of severe class II division II malocclusion receiving distraction of the posterior mandibular body (Fig. 48.6).

Mandibular symphyseal distraction

Mandibular symphyseal distraction is indicated for widening of the mandible, in which the amount of expansion exceeds that which can be achieved with conventional orthodontic or surgical treatment. Mandibular symphyseal distraction is also indicated in several orthodontic scenarios, such as severe anterior mandibular crowding, unilateral scissor bite, or impacted anterior teeth. However, the site for housing the distractor is limited and the amount of bone gained by widening is small. Fixation of the device could be tooth-borne or bone-borne.

The first generation of intraoral distractors was modified from the surgical-assisted rapid palatal expander.^{27,28} Thereafter, application of the DynaForm Distractor (Stryker Leibinger, Kalamazoo, MI, USA) in mandibular widening was reported.⁴⁵ This distraction system includes two compact distractor bodies capable of 7 mm or 12 mm maximal lengthening, which can be housed within the symphyseal region (Fig. 48.5a). At least two of the four flexible arms can be cut and bent to the proper length and shape according to the specific anatomic structure of the mandible. Fixation of the device can be either bone-borne or hybrid. At the time of removal, no incision is required. The arm can be simply pulled and the fork-ended terminal will release from its stabilization screw, which can be left behind without any need to open the wound. This has effectively converted the distraction process into a one-stage surgical procedure rather than the traditional two-stage surgery.⁴⁶

Tomcat and co-workers introduced two types of paramedial mandibular distractors – the Symphysis Distractor (Fig. 48.7a) and the Berger Distractor (Fig. 48.7b) (KLS Martin, LP, Jacksonville, FL, USA) – for correction of transverse mandibular deficiency associated with crowding of the anterior teeth in patients with class I or II malocclusion. The distractor is composed of a cylindrical body and a longitudinal gliding hole. Fixation is by miniplate and screws. The differences between the two distractors are the plate configuration and the length of distraction (15 mm for the Symphyseal Distractor and 10 mm for the Berger Distractor). The activation site is at the front to improve patient comfort. To ensure a simultaneous activation on both the alveolar and basal bone, this distractor has two occlusal splints incorporated to cover the buccal segments from the canine to the molar. The buccal part of the splint is attached to the upper miniplate of the distractor whereas the lower miniplate is fixed to the basal bone. The overall design is aimed to provide equal force to both the teeth and the basal bone and to avoid any occlusal interference and any TMJ problems during activation.⁴⁷ On the other hand, it is worth noting that the presence of this device may obliterate the space and interfere with re-attachment of the mentalis muscles.

In 2001, Mommaerts reported the use of a bone-borne Transmandibular Distractor (Surgi-Tec NV,

Fig. 48.6 A clinical case of mandibular body distraction. (a) Preoperative frontal view shows reduction in the lower facial third. (b) Preoperative lateral view shows hypoplasia of the mandible and chin. (c) Preoperative lateral cephalograph shows class II division II malocclusion. (d, e) Oral views show severe deep bite. (f) Lateral cephalographs show maxillary and mandibular teeth are decompensated. (g) Internal distractors fixed on each side of the mandible. (h) Class I occlusion achieved. Brugge, Belgium) for anterior mandibular widening.⁴⁸ This device is made entirely of pure titanium. It is composed of two vertical footplates connected by two threaded parallel distraction rods and a pair of off-set extensions, which can be bent to improve the plate adaptation (Fig. 48.7c). The extension allows the distraction rods to be exposed intraorally for activa-

tion. In addition, it allows a limited area for reattachment of the mentalis muscles. Two main distractor types are available in this system, which allow maximum expansion of 12 mm or 20 mm. Several subtypes are also available for better adaptation of the individual's chin contour.

Craniofacial distraction osteogenesis

With the advances of mandibular distraction, laboratory studies were performed to investigate the efficacy of distraction osteogenesis in other regions of the craniofacial skeleton. The first experiment on midface was not initiated until 1993, when Rachmiel *et al.* began midfacial distraction on a sheep model.⁴⁹ An external device was able to successfully advance the midface by 36 mm at the nasofrontal area and 43 mm at the lateral aspect of the maxilla. New bone regeneration was confirmed radiographically, clinically, and histologically. In 1995 Staffenberg demonstrated that the midface could be advanced using external distractors without the creation of maxillary osteotomies in growing animals.⁵⁰

Indications for craniofacial distraction osteogenesis

Distraction osteogenesis has been advocated in cases of severe mid-face hypoplasia requiring advancements greater than 10 mm. These have mainly included syndromic cases such as Apert, Crouzon, and Pfeiffer syndromes. Due to the large movement required, conventional surgical treatments of such deformities have been associated with instability and the need for bone

grafting. As such, craniofacial distraction osteogenesis is advantageous as it allows a large magnitude of movement without the need for bone grafting. It also allows the vector of movement to be adjusted in the horizontal and vertical planes. Similarly, distraction osteogenesis has been applied at the Le Fort I level, especially in cases of cleft maxillary hypoplasia or even in cases of severe developmental maxillary hypoplasia. Other applications of distraction osteogenesis at this level include correcting transverse width discrepancies and moderate to severe alveolar ridge deficiencies (alveolar distraction). The common clinical indications for craniofacial, midface, and maxillary distraction osteogenesis are listed in Table 48.2.

External maxillary and midface distraction

In 1996, Molina and Ortiz-Monasterio⁵¹ reported using an external facial mask resembling an orthodontic forward traction headgear following a Le Fort I osteotomy. However, Polley and Figueroa⁵² noted that an orthodontic facial mask with elastics was not sufficient to achieve the desired amount of forward movement. They developed a rigid external fixation system (RED; KLS Martin, Tuttlingen, Germany) (Fig. 48.8a) for maxillary advancement mounted on a halo frame fixed to the temporal portion of the skull. This serves to distract the midface forward or downward after maxillary osteotomies by anchoring to the maxillary dental arch via an occlusal splint. In a 10-year-old child presented with severe maxillary hypoplasia as a result of bilateral cleft lip and palate, Polley and Figueroa were successful in achieving a maxillary advancement of 15 mm with no complications or discomfort. They concluded that the device was simple to use and the scalp pins did not cause any problems. After 1 year, the position of the maxilla and occlusion remained stable. Similar external distractors with different color head frames but with the same mechanics were produced by Lorenz, called a blue system, and Synthes, called a gray system (Fig. 48.8b).

Instead of pulling the midface forward as with the previous mentioned midface distractors, Molina⁵³ designed a unilateral orbito-malar distractor (KLS Martin, Tuttlingen, Germany) (Fig. 48.8c) that pushes the facial skeleton forward and this can be used in conjunction with a Le Fort III osteotomy. The self-

Fig. 48.8 Examples of extraoral midface distractors. (a) Rigid External Distractor (KLS Martin). (b) External mid-face distractor (Synthes). (c) Molina Orbito-malar Distractor (KLS Martin).

contained rod is smooth and facilitates function and comfort. The activation portion of the rod exits percutaneously within the hair-bearing skin behind the ear and distraction up to 25mm is achieved. The anterior point of the device has a pivot point that enables flexibility in placement to the malar bone at the frontozygomatic process.

Internal maxillary and midface distraction

In 1995, Cohen *et al.*⁵⁴ introduced a system of miniature distractors that could be customized for use anywhere in the craniofacial complex. They initially reported on the use of these devices in a 4-month-old infant with unilateral craniofacial microsomia and anophthalmia. Facial moulages of the infant were taken to aid in the design of the device. A modified Le Fort III osteotomy with internal orbital osteotomies and a mandibular osteotomy were performed. The distraction devices were placed to correct the sagittal and vertical maxillary deficiency, expand the orbit and increase the length of the mandibular body. The vectors, chosen independently and the devices custom modified, enabled multiple distraction to proceed simultaneously. Cohen⁵⁴ further refined his miniature distraction devices, now called the Modular Internal Distraction (MID) system (Styker Leibinger, Michigan, USA) (Fig. 48.9a). Two distractor frames are available to provide 15mm or 30mm of advancement. The frames are attached to 1.7mm Wurzburg three-dimensional micromesh plates of varying sizes using 1.6mm screws. A flexible activation cable exits percutaneously either at the pre- or postauricular skin, through the scalp, or intraorally. It is recommended that a complete osteotomy be performed with a latency period of 5–7 days, followed by 1mm per day of distraction and a consolidation period of 8–12 weeks.

Sailer introduced the Zurich Paediatric Maxillary Distractor (KLS Martin, Tuttlingen, Germany) (Fig. 48.9b), which has two plates, one of which was attached to the maxillary tuberosity and posterior alveolus bone, and the other to the zygomatic buttress.⁵⁵ In a group of adolescents and adult patients, Bauman *et al.*⁵⁶ was able to achieve a mean advancement of 6.4mm (range 5–8mm) when measured at the A point. They noted that the intraoral distractors were well tolerated by all patients. Lauwers *et al.*⁵⁷ reported a case of severe maxillary hypoplasia in a

16-year-old cleft patient treated by maxillary advancement. Two intraoral distractors (Zurich Pediatric Maxillary Distractor, KLS Martin, Tuttlingen, Germany) were placed for a high Le Fort I osteotomy. After 12 months of postoperative follow-up, no bony relapse was detected and the occlusal result was stable.

Razdolsky introduced a ROD-4 distractor, which comprises a tooth-borne device attached to the distraction screw by a lock and key design.⁵⁸ This facilitates the insertion of a tooth-borne component preoperatively. A single case report has been published so far and a distraction of only 4mm was achievable in a non-cleft patient.

In 2004, Cheung *et al.*⁵⁹ reported the use of an intraoral bone-borne distractor (Synthes, Pennsylvania, USA) (Fig. 48.9c) in 15 cleft lip and palate patients. They found that the advanced maxilla was stable at 1 year follow-up. This type of maxillary distractor can be customized to meet the anatomical needs of the patients, based on preoperative treatment planning. It has four distractor lengths that allow 10mm, 15mm, 20mm, or 25mm advancement. Three anterior and posterior footplate heights are available to accommodate the pediatric and adult population. The distractors are made from stainless steel. They may be attached either directly to the maxilla or indirectly via a maxillary occlusal splint.

Gateño *et al.*⁶⁰ developed a new Le Fort I internal distraction device and was successful in advancing the maxilla of three cleft lip and palate patients with severe maxillary hypoplasia who needed advancement in excess of 12mm. The internal distraction device consists of an upper and a lower bone plate. The upper plate is shaped like a “U” and is installed above the Le Fort I osteotomy while the lower plate is shaped like an inverted “U” and is installed below the Le Fort I osteotomy. The anterior and posterior limbs of the plates are secured with screws to the pyriform and zygomatic buttress respectively. The distracting screw is oriented parallel to the sagittal plane and placed in the maxillary sinus. An activating rod is attached to the distracting screw with a universal joint and exits the oral cavity through the buccal mucosa.

Chin *et al.*⁶¹ designed an implantable internal titanium distraction device to achieve midface advancement. They custom designed their own internal device because they believed that patients would

Fig. 48.9 Examples of intraoral midface and maxillary distractors. (a) Modular Internal Distractor (Stryker Leibinger). (b) Zurich Pediatric Maxillary Distractor (KLS Martin). have a better acceptance and ease of integration. Models of the skeleton are milled from computed topographic data to plan the surgery and determine the vector of the internal distraction bone-borne device. The force is transferred from the temporal bone posteriorly to the midface through the lateral orbital rim and malar complex. Chin and Toth's surgical approach departed from the principles of Ilizarov by not observing a latency period but began activation immediately before closing the surgical site. They reported that 4–12 mm of distraction in the midface was achieved in their group of patients.⁶¹

An ingenious distractor using the maxillary sinus to hide the distractor has been marketed by Martin as the Nadjmi Trans-sinusoid Distractor (Fig. 48.9d). The distraction screw is fitted into the maxillary sinus. The upper and lower plates are fixed above and under the Le Fort I osteotomy line respectively. The head of the activator is put through the soft tissue just behind the upper lip.

Martin developed the Riediger Midface Distractor made of medical-grade titanium (Fig. 48.9e).⁶² It consists of a distraction cylinder with an internal expansion system and a lateral activation rod. A

bendable plate with four holes is connected at the posterior end. The lateral activation rod is constructed perpendicular to the distraction cylinder and is accessible through a small cutaneous incision in the preauricular region.

A case of maxillary distraction with an internal Synthes device at a Le Fort I level in combination with mandibular orthognathic surgery in a cleft lip and palate patient following by external rhinoplasty is illustrated to show the significant improvement both in esthetics and occlusion (Fig. 48.10).

Zygomatic distraction

Zygomatic deficiency is commonly seen in children with congenital deformities, such as craniofacial microsomia and Treacher Collins syndrome.

Previously, these patients were treated by recreating a zygomatic arch with either vascularized or non-vascularized bone grafts.⁶³ Many of these grafts either resorbed or failed to grow properly, and required serial grafting at a later age. Due to these problems, attempts have been made to augment the zygomatic complex by using the technique of distraction osteogenesis. In 1992 Phillips *et al.* reported the first animal zygomatic distraction using an external distractor on a canine model.⁶⁴ In 1994 Glat *et al.* confirmed that distraction of the zygoma could achieve good quality bone regenerate.⁶⁵ Molina *et al.*⁶⁶ reported the first successful distraction of an entire zygomatic complex using an internal distraction device that exited at the postauricular region. With this technique, they were able to advance the deficient zygoma forward as much as 10 mm.

(b) Preoperative lateral view shows protrusion of the lower lip and retruded maxilla. (c) Lateral cephalograph confirms hypoplasia of the maxilla and dentoalveolar hyperplasia of the mandible. (d) Class III malocclusion. (e) Teeth are decompensated. (f, g) Postoperative improvement in facial profile. (h) Intraoral maxillary distractors fixed on the maxilla. (i, j) Class I occlusion achieved.

Cranial distraction

Osteodistraction techniques have also been applied to the cranium. Persing *et al.* reported in 1986 on the possibility of coronal suture mobilization with a spring device on a rabbit craniostosis model.⁶⁷ They confirmed that advancement of the skull base across the frontosphenoidal suture was achievable by distraction in two cases.⁶⁸ This is particularly useful in patients suffering from craniostosis by reducing the complication of infection associated with immediate frontal osteotomy advancement.

Remmler *et al.* later applied a circumferential external distraction device to a rabbit craniostosis model.⁶⁹ A circumferential suturectomy was performed and this distractor advanced the craniofacial skeleton. Tschakaloff *et al.* reported that they could achieve coronal suture distraction with a subcutaneous device that was activated internally.⁷⁰ Muhlbauer⁷¹ reported in 1995 a group of patients with Apert syndrome, who underwent distraction osteogenesis of the midface and orbits for the correction of exorbitism and midface hypoplasia. He made use of bilateral screws lodged into the body of the zygoma and fixed posteriorly to the cranium. The device was placed percutaneously in the hair-bearing scalp above the ears. Results were reported to be excellent and were well documented by photographs and 3D CT scans.

Maxillary palatal distraction

Transverse expansion of the maxilla was first described in 1860.⁷² The combined surgical and clinical orthodontic treatment for maxillary expansion by a Hyrax appliance with anchorage on teeth became the standard rapid maxillary expansion method.⁶⁶ In 1999 Mommaerts⁷³ introduced a TransPalatal Distractor (TPD – Surgi-tech NV, Brugge, Belgium), the first bone-borne distractor successful in attaining maxillary transverse expansion by distraction osteogenesis. This device has interchangeable modules, which allow large expansion to be achieved even in narrow palates. Mommaerts emphasized that there is no loss of anchorage since the abutment plates are fixed on the palatal bone. This has later been trans-

formed into a 3-in-1 device to reduce the chance of component disassembly and to facilitate insertion (Fig. 48.11a). Recently, the Rotterdam Palatal Distractor and Magdeburg Palatal Distractor (KLS Martin, Tuttlingen, Germany) were developed (Fig. 48.11b, c). The Rotterdam Palatal Distractor is based on the mechanical principle of a car jack.⁷⁴ On activation, the nails of the abutment plates penetrate the bone and stabilize the device hence no screws are necessary for fixation of the device. This device is available in two sizes. Type A is designed for extremely narrow palates particularly in syndromal patients, whereas type B is for normal palates. Klaus and Zahl⁷⁵ reported use of the Magdeburg distractor. This device has to be fixed with screws to the palatal bone and can be applied submucosally or epimucosally. This device has proven to be useful in patients with acquired deformity. The Smile distractor was also recently developed by Titamed (Fig. 48.9d). This distractor is composed of two abutment plates and a cylindrical module. Conical, self-tapping osteosynthesis screws with hexagonal heads are used to fix the abutment plate. Different cylinder lengths are available to achieve expansion from 8–20 mm.

Alveolar distraction osteogenesis

Alveolar distraction osteogenesis (ADO) has the benefit of simultaneously increasing bone dimension, either in width or vertically, and the volume of surrounding soft tissues, particularly the attached gingiva of the alveolar ridge. Since its first report in 1996, ADO has been well recognized to have consistent evidence of bone augmentation clinically, histologically, and radiographically, thus making it a predictable, safe, and reliable surgical procedure for vertical bone augmentation with low incidence of major complications.^{76–83} The first report of ADO published in 1996 was of ADO applied to treat a vertically deficient alveolar ridge.⁸⁴ Since then it has been extensively used as one of the treatment modalities for bone augmentation in treating alveolar bone deficiency of both the mandible and maxilla prior to implant treatment. ADO is starting to gain popularity in reconstructing bone defects following tumor surgery. Favorable results of bone augmentation have been reported in cases involving vascularized flaps such as from the fibula.⁸⁵

Indications for alveolar distraction osteogenesis

The recommended clinical indications for ADO include:⁸⁶

- moderate to severe atrophy of edentulous ridge;
- segmental deficiency of the alveolar ridge that may compromise the esthetic and functional aspects of implant placement;

Fig. 48.11 Examples of palatal distractors. (a) TransPalatal Distractor (Surgi-Tec). (b) Rotterdam Palatal Distractor (KLS Martin). (c) Magdeburg Palatal Distractor (KLS Martin). (d) Smile Distractor (Titamed).

- narrow alveolar ridge;
- ankylosed submerged teeth such that orthodontic movement is not feasible;
- osseointegrated implant that is at a higher gingival line than adjacent teeth.

Besides the indications proposed above, Garcia *et al.*⁸⁷ recommended vertical ADO whenever the ratio of required crown height to bone height available for implantation is greater than one.

The advantages of ADO in comparison to conventional surgical bone augmentation techniques are that ADO is minimally invasive, there is a shorter period for rehabilitation with implant, the bone graft procedure is eliminated thus avoiding donor site morbidity, augmentation is more physiologic with natural bone regeneration simultaneous with soft tissue expansion, and there is a lower rate of complications.^{76,77,80–82,88–93}

However, ADO also has several disadvantages, such as the long duration of treatment, involving two surgical procedures, it is considered to be technically complex, and it is also difficult to perform in a limited alveolar space.^{77,88,92,94,95}

Vertical alveolar distraction

The most common vertical distractor used is TRACK design (KLS Martin Group, Tuttlingen, Germany) with two titanium miniplates connected by a central activation rod, either 10 or 15 mm in length. The problem of lack of stability, particularly from the lingual pull by the tongue muscle and palatal pull by the tight palatal mucosa, has prompted a modified design with the addition of a stabilization plate at right angles from the other plates at the base of the cylindrical rod (Fig. 48.12a). Alternatively, Chin designed a distractor called LEAD (Stryker Leibinger, Kalamazoo, MI, USA), with the rod passing through the alveolus and separating the miniplates, thus achieving distraction. A distractor was purposely developed for vertical distraction of the edentulous ridge by Groningen (KLS Martin Group, Tuttlingen, Germany) composed of two microscrews for activation and a position screw to minimize rotation of the fragment. Medartis and Synthes have successfully incorporated an angulating device to the distractor. In the Synthes design, there is a small green screw at the bottom of the activating rod to adjust the vector angulation (Fig. 48.12b, c). In the Medartis design,

Fig. 48.12 Examples of alveolar distractors. (a) Alveolar ridge TRACK Distractor (KLS Martin). (b) Alveolar Distractor (Synthes). (c) Alveolar Distractor with vector angle adjusted (Synthes). (d) Crest Expander for transverse expansion of ridge (frontal view; Surgi-Tec). (e) Crest Expander (bird's-eye view; Surgi-Tec).

there is a thin rod running parallel together with the activating rod; this enables postoperative distraction of the upper fragment if needed. Surgi-Tec developed a robust vertical distractor that also allows simultaneous heightening as well as transverse movement of the distracted fragment. However, the vertical distraction length is limited to 10mm at a time and the tissue needs to be reopened for anything more than 10mm (up to 20mm).

Vertical ADO can be performed under either local anesthesia, intravenous sedation, or general anesthesia. The procedure involves an intraoral incision at the buccal vestibule, without lateral releasing incisions. Subperiosteal dissection should be performed to obtain adequate visibility of the underlying bone, but no mucoperiosteal dissection toward the alveolar crest and on the lingual side is required to preserve adequate blood supply for the osteotomized bone segment.

The intraoral distractor should be adapted to the planned site before the osteotomy. The bone segment can be completely separated from the basal bone using an oscillating saw or a surgical bur. The distractor is then fixed with mini-screws to both the basal bone and the osteotomized segment.

The osteotomized segment should first be activated by the distractor to check the direction of distraction and freedom in movement. Once movement in the line of distraction has been checked, the osteotomized segment should be repositioned with bone-to-bone contact until it is ready for the active distraction phase.

Transverse alveolar distraction

There are only two transverse alveolar distractors present on the market. One was developed in Japan and one by Surgi-Tec from Belgium. The Alveo-Wider from Japan consists of a malleable titanium mesh placed on the labial cortical plate and activation is by a small screw passing through the mesh and buccal plate to reach the lingual plate. Since the lingual plate is stable, on activation the buccal plate will be pushed laterally thus creating a distraction gap for bony regeneration. The mesh and micro screw are then removed at the time of implant placement. In contrast, the Crest Expander from Belgium is a flat device with four prongs sticking out at the bottom (Fig. 48.12d). The device is inserted following a similar osteotomy to that previously described but inserted from the crestal side rather than the buccal side (Fig. 48.12e). The low profile is advantageous to avoid any occlusal interference from the opposing teeth.

Transverse ADO or alveolar widening can be done either in one or two stages. For both procedures, it is normally done under local anesthesia where a crestal mucoperiosteal incision is made followed by buccal vertical mucoperiosteal incisions placed anterior and posterior to the distraction zone.

The crest itself is minimally exposed and a round bur is used to make a small trough along the crest. Bone cuts are made through the trough, and through the anterior and posterior vertical incisions with minimal stripping of mucoperiosteum using a sagittal micro saw or piezoelectric ultrasonic bone cutter. The use of piezoelectric bone cutting tools is particularly convenient for splitting of the thin alveolar ridge with minimal loss of residual bone.

An osteotome is normally used crestally and a "green-stick" fracture is produced in the buccal plate. The distractor is tapped into place before the wound can be approximated with sutures. For a two-stage procedure, the bone cuts are made during the first visit and the distractor will then be placed at the second stage. As in other distraction procedures, patients will undergo latency, distraction, and consolidation periods as described in the previous section. Removable prostheses are not allowed in the distracted areas until the distraction device is removed. It was also suggested that the ADO protocol should consider an overcorrection of more than 25% within the limits of the applied surgical protocol.⁹⁰

The duration of the consolidation phase seems to be the major factor that determines the duration of the overall treatment period and primary stability of implants placed at the augmented region.⁸⁰ Studies by Saulacic and Turker indicated that a period of 12 weeks is sufficient for bone maturation and for the site to be ready for implantation.^{80,81} However, another study suggested that implants could be placed in a distracted region within 4–8 weeks postoperatively because distraction osteogenesis heals faster than the time required for autogenous bone graft.⁸²

In the systematic review by Saulacic *et al.*,⁸⁰ the mean osseointegration period of 469 implants (dental implants and prosthetics treatable distraction implants) was 4.59 ± 1.34 months (range 3–8 months) with an overall success rate of 97%. ADO can provide a limitless vertical bone augmentation restricted only by the length of the vertical distractor design. A report on the ability of ADO to increase the width of the alveolar ridge in a transverse direction has been published by Laster.⁸² In that study, alveolar width in the range 4–6mm was successfully gained. The authors have successfully performed 20mm fibular distraction for heightening of mandibular defects.

It has been reported that ADO was successfully performed to gain both width and height to allow placement of 14mm implants in an initially narrow maxillary ridge.⁹⁶ A study conducted by Enislidis showed a high survival rate (95.7%) of implants following ADO.⁹² This was also supported by studies done by Chiapasco *et al.* and Jensen *et al.* with 100% and 90.4% implants survival rate, respectively.^{77,78} Recently, Uckan *et al.* also demonstrated that the survival rates of implants in bone regenerated by intra- and extraoral distraction were comparable, reaching 88% and 94%, respectively.⁹³

Although bone resorption in ADO was reported during the peri-implant stage, the incidence was consistent with implants placed in normal bone. The survival and success rates of implants were also comparable to cases in normal bone.⁸⁸ It was demonstrated that the distraction regenerate has a better ability to maintain the regenerated bone gained when compared to guided bone regeneration.⁷⁷ Thus, ADO is better in terms of achieving a long-term prognosis in maintaining bone gain while having similar peri-implant resorption to normal bone.

In a study to evaluate patients' perceptions of the technique, it was concluded that ADO had a high degree of acceptance among patients. The technique was rated as a much better procedure than conventional bone graft surgery among patients who had undergone both surgical procedures.⁹⁵

Temporomandibular joint distraction

Temporomandibular joint (TMJ) reconstruction is usually performed following removal of pathologies/diseases which affect the normal anatomic relationship of its core components: mandibular condyle, articulating disc, and glenoid fossa. The most common pathology is TMJ ankylosis, while other conditions which necessitate TMJ reconstruction include: advanced joint arthritis, degenerative changes, and benign neoplasm. The mandibular condyle is commonly involved in all the above conditions, and often needs to be excised. As a result, rebuilding of the condyle is regarded as one of the most important aspects in TMJ reconstruction.

The concept of TMJ distraction is that a neocondyle can be created in the ramus bone after loss or resection of the original condyle. A bony segment is made on the posterior mandibular ramus and then moved gradually towards the corresponding glenoid fossa guided by a distractor device in order to restore the normal anatomical relationship. This concept was first presented by Stucki-McCormick in 1997⁹⁷ and

was supported by an animal study, in which the neocondyle created could provide satisfactory biomechanical properties for normal functional loading.⁹⁸ Today it is a well accepted treatment modality for adult patients with good long-term stability and TMJ function.³³ In children, despite promising short-term results, current clinical evidence is limited by the relatively short follow-up period with respect to the long potential growing period of the mandible.⁹⁹ Nevertheless, a recent animal study has demonstrated the growth potential of the neocondyle created by transport distraction, particularly when the neocondyle is under functional stimuli.¹⁰⁰

The main goal of condylar distraction is to create a neocondyle in good anatomic relationship with the glenoid fossa. Unlike maxillary and mandibular distraction, in which the final distraction segment can be modified slightly by occlusal elastics, the final position of the neocondyle is highly dependent on the distraction vector. Good precision is necessary during the planning stage. 3D surgical planning using a stereo-model is therefore highly recommended. The advantages of stereo-model planning include:

1. Allows surgical simulation for resection of pathology and assessment of the extent of defect.
2. Helps the design of the distraction trajectory and the position of the distractor, by providing clear anatomic information of the surrounding vital structures.
3. Give good visualization of the glenoid fossa to estimate any further adjustment required for good housing of the future neocondyle.
4. Makes further 3D planning possible in situations when correction of additional dentofacial deformity is required apart from the TMJ reconstruction; in these cases combination of the stereo-model and dental casts is necessary.
5. Enables fabrication of vector-locating splint and titanium glenoid fossa for transfer of the planning information to the surgical environment.
6. Provides an excellent tool for surgeon-patient communication.

Fig. 48.13 Temporomandibular joint distraction. (a) L-osteotomy of posterior ramus, gap arthroplasty with titanium fossa and location of unilateral mandibular distractor (Synthes). (b) Simulation of the condylar distraction from activation of the distractor. (c) Localization of distractor with the aid of vector-locating splint.

On the stereo-model, a reverse-L osteotomy is designed in the posterior mandibular ramus behind the mandibular foramen. The dimension of the osteotomy segment should allow sufficient area of screw placement for fixation of the distractor on both ends (Fig. 48.13a). Sometimes minor shaving along the gonial angle is required to provide better adaption of the distractor arm. A titanium glenoid fossa can be fabricated if there is any risk of perforating the thin bony fossa. Upon completion of the distraction simulation (Fig. 48.13b), a vector-locating splint is fabricated³³ to register the distractor's position and angulation over the mandibular ramus and the gonial angle region (Fig. 48.13c).

Similar to presurgical planning, the placement of the distractor is usually the last stage of the surgery. While a preauricular approach is indicated for the excision of pathology affecting the TMJ, a submandibular approach is indicated for the placement of the distractor. Surgical access to the mandibular ramus for distractor placement is gained by a 3cm submandibular incision around the gonial angle. The preadapted distractor is placed on the lateral mandibular ramus, with the location being guided by the vector-locating splint. Temporary fixation is achieved with one screw placed on each end of the distractor. The outline of the osteotomy cut can be marked with a surgical bur before the distractor is removed. A reverse-L osteotomy is then completed using a surgical bur followed by an osteotome. Minimal mobilization is advisable in order to avoid any excessive detachment of the medial pterygoid muscle from the osteotomized bone segment. The distractor is oriented to the planned position and fixed with two to three screws on each side, guided by the vector-locating splint. The distractor is activated and tested before the wound is closed, to ensure that the transported segment is activated smoothly.

A 7-day latency period is recommended before the distractor is activated. A daily activation rate of 1 mm can be divided into two to four rhythms per day. A check radiograph is recommended 3–5 days after the initial activation to confirm that the osteotomy segment has been properly separated from the ramus. During the activation phase, the patient is encouraged to perform regular jaw exercises. The completion of activation is determined: (1) clinically, by checking for any sign of posterior open bite developing on the activation side; and (2) radiographically, using a panoramic radiograph to check whether the distracted bone has reached the desired docking location. At the end of the activation phase, the distractor is rewinded 1–2mm backward to avoid direct bone contact between the distracted bone segment and the glenoid fossa. A panoramic radiograph should be taken to confirm the position of the transport segment docking in the glenoid fossa.

During the consolidation phase, patients should be reviewed regularly until radiograph signs of bone refilling in the distraction gap. The distractor should

Fig. 48.14 A clinical case of temporomandibular distraction on a patient with TMJ ankylosis. (a) Preoperative frontal view shows inability to open the jaw. (b) Postoperative frontal view shows 50mm mouth opening. (c) Preoperative panoramic radiograph shows enlargement and fusion of right condyle. (d) Panoramic radiograph shows activation of the distractor. (e) Radiograph taken after removal of distractor shows bone regeneration along the distraction gap.

preferably be removed under general anesthesia. The most convenient way of gaining access to the distractor is via an intraoral approach using the previous incision line. An endoscope using a transbuccal route can also help to confirm bone formation in the distraction gap and to localize the screws during removal. The distractor is removed via the oral route, and the transcutaneous opening is then refreshed and closed primarily. A classical case of TMJ ankylosis

with reconstruction of the condyle by distraction is illustrated in Fig. 48.14.

Bone transport distraction

Extraoral devices for mandibular bone transport

The feasibility of bone transport in mandibular reconstruction was first presented by Costantino in 1990. Following a number of animal experiments proving successful regeneration of a bone segment bridging the defects, Costantino presented the first clinical report of bone transport for reconstruction of a segmental defect in 1995.¹⁰¹ An extraoral appliance was used, which was composed of a semi-circular external frame attached by two pairs of pins to the mandibular segments and a transport tram connected to the bone transport segment.

Using a distraction lengthening device attached to a reconstruction plate (Synthes, Paoli, PA, USA), Block presented four cases of bifocal distraction osteogenesis for mandibular reconstruction.¹⁰² A 7-day latency period was allowed before activation of 0.5 mm twice daily. The findings showed satisfactory

bony reconstruction without the need for bone graft, and successful recreation of the alveolar ridge and oral mucosa regeneration. In 1997, Fedotov reported the result of transport distraction using a semicircular apparatus on 22 patients with post-traumatic defects varying in size from 10–180 mm.¹⁰³ Depending on the size of the defects, the approach in bone transport would vary from monofocal, bifocal, or even trifocal distraction. In cases of trifocal distraction, two transport discs were created and distracted towards each other until they met. Further distraction can compress the transport discs at the docking sites with each other achieving body union forming a continuous mandibular bridge.

In 1997, Klein reported the use of a Frankfurt Craniofacial Distraction System (Normed Medizin-Technik GmbH, Tuttlingen, Germany) in six patients for reconstruction of mandibular defects.¹⁰⁴ This distractor was composed of a U-shaped gear rod for connection to the individual distractors and stabilizers (Fig. 48.15a). Fixation was achieved with transosseous pins. A 5-day latency period was allowed before activation of the device at the rate of 1 mm per day. Once the transport segment reached the docking site, a second surgery was required to clear the soft tissue from between the transport and normal bony

Fig. 48.15 Examples of mandibular bone transport distractors. (a) Frankfurt Craniofacial Distraction System (Normed). (b) DynaForm Intraoral Distractor with reconstruction plate (Stryker Leibinger). (c) Herford Transport Distractor (KLS Martin). (d) Threadlock Transport Distractor (KLS Martin).

segment before further activation to achieve compression union and the subsequent mandibular reconstruction without bone grafting.

It is noteworthy to point out that the above devices for mandibular bone transport are all made of bulky U-shaped external stainless steel rigid frames, which form the path of bone transport simulating the natural curvature of the mandible. Surgeons quickly became aware that the distraction regeneration always ends up in a linear bony bridge irrespective of the distraction pathway. When a transported disc of bone is moved along a curve, the collagen fibers within the distraction site always follow a straight line pattern regardless of the curve on which the transport took place.³⁸ Therefore, recent extraoral bone transport devices are based on a combination of customized assemblies of multiplanar distractors and reconstruction plates. Both the Multi-Vector Mandibular Distractor (Fig. 48.3g) and 3D Xternal Distraction System (Fig. 48.3h) can achieve a linear activation of up to 85 mm. In addition, the use of a light-weight carbon fiber rod greatly enhances patient comfort during the consolidation period and frees the distraction body for application in a different patient.

Intraoral distractor for mandibular bone transport

The clinical application of an intraoral distractor in bone transport was first described by Guerrero *et al.* in 1995¹⁰⁵ using the DynaForm distractor in combination with a reconstruction plate (Fig. 48.15b).

In 2004, Herford reported the use of a plate-guided distractor in four patients for reconstruction of a segmental mandibular defect.¹⁰⁶ The Herford Transport Distractor (KLS Martin, Jacksonville, FL) is an intraoral device that is secured via a titanium mesh to a reconstruction plate with a screw on one end and a transport bone segment on the other (Fig. 48.15c). A series of distractors for a maximal range of bone movement from 30–60 mm is available in this system. The superior portion of the mesh can be secured to the transport bone segment whereas the inferior portion is adapted around the plate. A screw-activated internal design combined with multiple swivel joints enables the transport segment to move along the track of a reconstruction plate to achieve distraction of a curved segment from the midline of the mandible all the way to the ramus. In addition, the same manufacturer also provides the Threadlock Transport Distractor which allows reconstruction of a straight mandibular continuity defect in the range of 30–50 mm (Fig. 48.15d).

Maxillary transport distraction

Liou developed a distractor for alveolar cleft transport (Fig. 48.16a). The Liou Distractor (KLS Martin Tuttlingen, Germany) can be used for the following

circumstances: bilateral or unilateral wide alveolar cleft or oronasal fistula in bilateral cleft lip and palate patients; maxillary alveolar bony defect due to trauma; creating interdental edentulous space to relieve maxillary dental crowding; and maxillary lengthening for maxillary hypoplasia. The device is available for left or right alveolar clefts in 15 mm and 20 mm sizes. In patients with posterior maxillectomy defect, a bone-borne transport distractor was designed by Cheung *et al.* (Fig 48.16b).¹⁰⁷ The custom-made transport distractor is based on a stereo-model generated from CT scan data. This device is made of stainless steel and was designed and manufactured by the industrial center at the Hong Kong Polytechnic University. The design is similar to the fourth-generation distractor used in their pilot study on monkeys.⁷⁵ The distractor consists of a cylindrical distractor body and three extension arms with two stabilization arms and one transport arm. The distractor can generate up to a 15 mm distraction path and is activated by a flexible distraction rod connected to the front end of the distractor body (Fig. 48.16c). The two stabilizing arms extend to the zygoma body and the pyriform bone, respectively. The transport arm is fixed to the transport segment by a threaded screw and there are four screw holes designed in serial direction for fixation to the bone transport segment. On activation the distractor can move the transport arm linearly along the distractor body via a distractor rod rotated in a clockwise direction. The distractor arms are prebent and simulated to the planned position on the patient's stereo-model.

Complications

The hypothesis that distraction osteogenesis is an uncomplicated procedure has been undermined by the reported complications that occurred among patients who underwent distraction in the maxillofacial region. The rate of published complications in distraction osteogenesis can vary from 27.7% to 40%.^{79,108} In general, complications can occur in four different stages: intraoperative, latency, active

Fig. 48.16 Examples of maxillary bone transport distractor. (a) Liou Distractor (KLS Martin). (b) Cheung's Posterior Maxillectomy Transport Distractor. (c) Maxillectomy distractor under activation.

Table 48.3 Possible complications reported at different stages of distraction osteogenesis.

Stages	Types	Complications
Intraoperative	Device	Excessive length of the threaded rod Fracture Unstable placement
	Non-device	Excessive bleeding Fracture of the transport segment Incomplete fracture Jaw fracture Nerve transection
Latency period	Device	Loosening of distractor
	Non-device	Epistaxis Infection Wound dehiscence Skin irritation Diplopia Hypoesthesia Blindness
Active distraction	Device	Incorrect vector direction of distraction Breakage or loss of the distractor Osteitis around screws
	Non-device	Dishisence of the mucosa by the transport segment Wound dehiscence Skin fenestration Infection Pain during active turning of distractor Malnutrition Premature consolidation Temporomandibular joint pain
Consolidation	Non-device	Fibrous union Delayed wound healing Malunion Relapse Persistent nerve damage Infection Condylar resorption Hypertrophic scar

distraction, and consolidation (Table 48.3). These complications can be either device related or non-device related. The persistence of complications may be short or long term.

The activation rod has been reported to be one of the main sources of complications, presenting commonly as facial scars or recurrent infection around the rod exit (Fig. 48.17). These may result in disappointing outcomes for patients and surgeons.^{93,95} Other major complications such as fracture of proximal or basal bone were minimal. Long-term complications, including blindness, diplopia, TMJ pain, permanent nerve damage and neurological alteration, have been reported in the literature.^{59,79} Idiopathic condylar resorption of the TMJ related to mandibular distraction may occasionally occur resulting in anterior open bite and sleep apnea (Fig. 48.18).

**Fig. 48.17** Common complications related to distractors. (a) Facial scar from extraoral distractor retention and traction. (b) Intraoral infection around an activation rod.

In vertical ADO, complication rates vary from 66–100%.^{92,109–111} However, vector displacement has become one of the most frequent unpredictable complications that has unfavorable impact on dental implant placement.^{93,110} This may be due to mylohyoid and genioglossal muscle traction at the floor of the mouth, shape of the mandible, and lingual periosteum that attaches to the osteotomized segment acting as a hinge.¹¹⁰ Enislidis *et al.* reported that 37.8% of 45 distraction regions suffered from soft tissue dehiscence.⁹² Perdijk reported that fracture and decreasing residual bone height are the most common complications associated with ADO in atrophic mandibles, and these normally occur within the first postoperative year.¹⁰⁹

There are non-surgical issues that need to be taken into consideration when deciding whether a patient is suitable for this procedure. Financial consideration, which involves the cost of the distractor, and patient and family member's compliance to activate the distractor also play a major part in contributing to successful surgical outcome. Different complications may lead to different consequences. For example, intraoperative complications may lead to an extended surgery time, thus increasing the patient's morbidities. Vector problem may lead to occlusal interference and instability. In severe complications of vector malalignment, leading to anterior open bite, the patient may require reoperation for adjustment of occlusion.

It is important for surgeons to understand the causes of these complications so that they know how to prevent and treat them when necessary. Prophylactic antibiotic treatment and adequate mucosal closure can help to minimize infection around the distraction wound. Wound dehiscence can be minimized by smoothing the sharp edges of the transported fragment. If wound dehiscence occurs postoperatively despite the above measures, resuturing of the soft tissues should be done as early as possible to prevent the spread of infection and necrosis of the distracted bone. Neurosensory deficits can be minimized by correct execution of the osteotomy and placement of fixation screws. Resorption of the transported fragment can be minimized by an overcorrection of distraction or the use of elastic to unload the TMJ. Fractures of the transported fragment or basal bone can be minimized by correct use of osteotomies without undue force. Distraction should be stopped and the fracture treated with osteosynthesis if a fracture is identified during the operation.

Fig. 48.18 Fibrous union and relapse of occlusion from mandibular distraction in a case with previous infection around distractor rod. (a, b) Apparently satisfactory healing and occlusion from intraoral mandibular distraction. (b, c) Relapse of occlusion to class II open bite shortly following removal of mandibular distractor.

Device-related complications may also cause serious unfavorable results. These include consolidation delay, fibrous union, and malunion. These can be largely prevented with an appropriate distraction rate and vector, correct stabilization of the distractor, and complete segmental osteotomy. Other conditions such as deviation from the correct distraction vector can be minimized with prior evaluation of the mucosal thickness and vestibular or lingual muscle insertion. Proper evaluation of the occlusion and avoidance of bone segment interference can prevent device fracture. If it occurs, immediate stoppage of distraction and fragment repositioning should be performed.

When unfavorable outcomes develop, the treatment strategy should be changed according to the severity and type of complications. Further delay of the distractor removal until consolidation can be attained in cases with large distraction and in medically compromised patients. In serious conditions, such as open bite from vertical ramus distraction, distraction surgery may need to be repeated with the consent of the patient.

Research and development in maxillofacial distraction

Distraction osteogenesis was originally applied to craniofacial syndromes in children and in clinical

cases beyond the biological limits of conventional orthognathic surgery. It was soon realized that distraction cannot replace conventional orthognathic surgery because distraction cannot achieve impaction, constriction, or retrusion of the bony segments. Through the experience of surgeons working in the cranio-maxillofacial region, the scope for clinical applications has increased and indications as well complications with this technique have been gradually defined.

There has been an explosion of distractor designs available on the market in the last 17 years. Further development is limited by the intermittent mode of distraction activation and the mechanical age may soon be replaced by biological modulation of distraction for compromised tissues and hosts. Emerging results of distraction from some new research directions are further elaborated below.

Administration of growth factors to enhance bone healing

Bone healing during distraction osteogenesis can be affected by many factors including the type of osteotomy, timing and rate/rhythm of distraction, stability of fixation, age of the patient, and underlying disease. Although there have been efforts to improve osteotomy techniques and stability of fixation, the overall treatment of bone lengthening still takes a long time.

The patient has to tolerate wearing a distractor for several months until the lengthened segment can bear the mechanical load. From the clinical perspective, surgeons in maxillofacial and orthopedic surgery would like to be able to reduce the lengthy treatment course.

Reduction in the consolidation period or increases in the distraction rate are possible options for reducing the treatment time. The biological environment created by distraction at a routine rate is superior to that with a rapid distraction rate.¹¹² A higher rate of distraction impairs angiogenesis and inhibits the expression of osteogenic growth factors, such as bone morphogenic proteins 2 and 4, leading to poor bone quality (Table 48.4).^{112,113} Great efforts have been made by researchers and clinicians to promote bone formation during distraction osteogenesis by local and systematic administration of angiogenic and osteogenic growth factors or cytokines, including bone morphogenic protein (BMP), transforming growth factor beta (TGF- β), platelet-derived growth factor (PDGF), vascular endothelial growth factor (VEGF), and fibroblast growth factor (FGF). Among all these growth factors and cytokines, BMPs play the most important role in bone healing and regeneration by inducing the osteogenic differentiation of mesenchymal stem cells, and have a synergistic effect with the angiogenic growth factor, VEGF. On a rabbit model of mandibular lengthening, recombinant human (rh) BMP-2 has been confirmed to enhance bone ossification at both routine and rapid distraction rates (Fig. 48.19). The addition of rhBMP-2 is able to compensate for the rapid distraction rate in distraction osteogenesis.¹¹⁴ The administration of growth factors and cytokines has demonstrated a promising way to accelerate bone healing resulting in a reduced treatment course. The effective delivery method, cost effectiveness, and biological safety still need further investigation.

Resorbable distractor

The parallel development of resorbable surgical materials and the application of distraction osteogenesis have led to merging of these technologies in the development of single-stage resorbable distractors. Interest was stirred in resorbable materials with the realization that mixing two different types of poly-

mers would result in markedly different resorption characteristics depending on the proportions of each polymer. These polymer macromolecules, when properly formulated, can serve a structural function and are then gradually degraded and resorbed by the body. Cohen *et al.*¹¹⁵ published the initial work using a maxillary distraction device made of a resorbable polymer in 2000, and this was followed with a series of new devices allowing one-stage distraction of the craniofacial skeleton. Resorbable mandibular distractors, when combined with advances in resorbable materials and distraction, may enable predictable distraction with a single operation.

The currently used polymers are not as strong as the equivalent volume of titanium. Therefore, resorbable devices tend to be thicker and bulkier. Rather than bending as is done with titanium plates, the resorbable materials are thermally sensitive and can be molded into a 3D shape after they are heated in a sterile water bath. This experience has led to the recognition that successful application of resorbable distraction requires modifications of the techniques used in the application of metallic distraction.

Continuous distraction osteogenesis

The quality of the newly formed bone by mechanical traction is highly related to the rate (the amount of bone lengthening in millimeters per day) and rhythm (in how many steps each day should the rate be achieved) of distraction. For a given rate of distraction, a higher rhythm of distraction has been confirmed to improve bone formation. Automatic distraction systems that can activate a high frequency or so-called continuous distraction provide a promising alternative in distraction osteogenesis. Micro-motor, micro-hydraulic cylinder, portable syringe, and infusion pump have been used to drive the distractor.^{116–119} Bone healing is accelerated after continuous distraction when compared with intermittent distraction. A major problem hindering the wide clinical use of automatic distraction systems is their size and weight.

A recently developed miniaturized automatic driver using the core of a clock, consisting of a high-torque movement circuitry, a step motor, and a gearing system, has been used to achieve an extremely

Table 48.4 Qualitative analysis of BMP-2 and -4 expression during rabbit mandibular distraction osteogenesis at different times.

Time of sacrifice	Osteoblastic cells		Fibroblastic cells		Vascularized fibrous matrix

Fig. 48.19 The effect of rhBMP-2 injection on distraction regenerates under normal and rapid rates of distraction. Under routine rate distraction, plain radiograph, micro CT, and histological examination show obviously more bone formation in the BMP injection sides (d-f) than in the control sides (a-c). Under rapid rate distraction, bone formation is also significantly accelerated in the BMP injection sides (j-l) than in the control sides (g-i). (CT = cartilaginous tissue; FT = fibrous tissue.)

high frequency distraction of eight steps per second (Fig. 48.20).¹¹⁵ This automatic driver is an independent system and does not need a specially designed distractor. Using the specially designed mounting mechanism at the end of the flexible shaft, the automatic driver can be easily attached on most clinical distractors. The rate can be decreased or increased by adjusting the speed of the circuitry. This automatic driver not only demonstrates a great potential for further clinical application, but also provides a very useful tool to study the vascularization and molecular-biological modulation of high-frequency

distraction. Study has shown that high-frequency distraction upregulates gene expression of angiogenic growth factors, such as VEGF (Fig. 48.21) resulting in enhanced angiogenesis (Fig. 48.22) and osteogenesis (Table 48.5).

Currently, surgeons can only examine the distraction progress and the mechanical condition of the distractor in person, which means frequent clinical appointments with the patients. It will save much time and trouble if the doctor can check the data feedback from the distraction system and adjust the treatment protocol at a distant site. With the possible availability of a remote-controlled distraction system, capable of transmitting information through the internet, surgeons could supervise patients more easily and provide instant treatment modification if needed. The automatic driver system in combination with remote-control technology would provide a change in the future application of distraction osteogenesis.

Chapter 49a

Craniofacial Syndrome Patients – Reconstructive Surgery

Peter Tarnow

The chapter is an overview of reconstructive surgery in craniofacial syndrome patients. Craniofacial surgery deals with congenital deformities, trauma, and tumors of the craniofacial skeleton and the surrounding soft tissues. This chapter will present the symptoms and treatment of craniosynostosis and craniofacial syndrome patients focusing on cranial and upper facial surgery. The type and timing of surgical interventions are discussed, as well as the importance of dedicated team work.

Introduction

The term craniofacial syndrome refers to patients born with a pattern of disease that involves the craniofacial skeleton. This may involve the premature closure of sutures in the cranial vault, the cranial base, and in the midface, leading to growth disturbance, abnormal function, and distorted appearance. Many carry identifiable genetic markers that are often used in diagnosis. Similar terms, which may be used interchangeably, are craniofacial dysostosis or craniofacial dysostosis syndromes. Craniofacial syndromes are rare and often hereditary, the more common among these are the syndromes described by Saethre–Chotzen,

Crouzon, Apert, and Pfeiffer, which are named accordingly.

Craniofacial surgery is a collection of advanced techniques for reconstructive and restorative surgery for patients with craniofacial malformations. The French plastic surgeon Paul Tessier is considered by many to be its father,¹ having pioneered many novel techniques which are still used today. In these patients, craniofacial surgery aims to improve function, development potential, and appearance by repositioning the bones of the face and skull through osteotomies as well as manipulation, reconstruction, or augmentation of soft tissues. Scarring is minimized using incisions that are easily hidden. The techniques and philosophies have now spread around the world and numerous centers of craniofacial surgery have been established to take care of and treat these patients. Since its inception craniofacial surgery has expanded and evolved tremendously. Techniques have been refined, indications standardized across the world, and more consistent outcomes achieved. Craniofacial surgeons also provide comprehensive treatment of craniofacial trauma, malignancy, and periorbital surgery, and often perform facial esthetic surgery.

A team approach to the treatment of these patients and their families significantly improves outcomes and cannot be emphasized enough.² The days of isolated surgeons dabbling in craniofacial surgery are over. A specialized surgical team must include craniofacial surgeons, neurosurgeons, oral surgeons, anesthesiologists, ophthalmologists, and otolaryngologists. Dentists, orthodontists, pediatricians, and allied medical professionals all contribute significantly. All must have an interest in craniofacial surgery and be able to provide long-term commitment to the regular follow-up of patients and their families. All should contribute to a longitudinal treatment plan which maximizes the growth potential and development of the child as well as functional and esthetic outcomes. It is important to recognize that the end result of surgery may not be apparent for many decades after any intervention and that long-

term follow-up and accurate record keeping are required. Decisions regarding the timing of interventions are critical as the operations influence growth outcomes. For example, the child's ability to quickly reossify calvarial defects during the first year of life can be taken advantage of by timing any skull osteotomy surgery at this age to allow rapid healing. On the other hand, early interventions in the upper and lower jaws may diminish their growth potential substantially by causing restrictive scarring and may cause long-term secondary deformity.

Diagnosis and preoperative evaluation are based on clinical examination. Three-dimensional computed tomography (CT) scans are routinely used for diagnosis, planning, and follow-up, but a range of diagnostic tools may help each patient depending on the specific situation.

Craniosynostosis

Craniosynostosis is a major feature of most craniofacial syndromes, and a comprehensive understanding of it is necessary to provide adequate treatment. Craniosynostosis is the premature fusion of one or more cranial sutures which results in growth disturbances of the skull. The growth is restricted perpendicular to the fused suture, as first described by Virchow in 1851.³ It is a relatively common disorder with a birth prevalence of about 1/2000–2500 newborns.⁴ Craniosynostosis will lead to morphologic skull and face deformities, but can in addition affect intracranial pressure with psychological or functional consequences like learning disabilities, visual and hearing impairment or loss, or even death.

At this time the treatment of craniosynostosis still remains surgical despite significant progress in the understanding of genetic and molecular biology involved in the malformations.⁵ Craniosynostosis syndromes are often a result of mutations in fibroblast growth factor receptor genes FGFR-1, FGFR-2, and FGFR-3, or mutations in transcription factors TWIST and MSX2.⁴ The fate of cranial sutures is, however, a complex process involving the dura mater, periosteum, sutural mesenchyme, and bone. Molecular signaling by different growth factors and their receptors, bone morphogenetic proteins and their inhibitor noggin, and extracellular matrix components all take part in cranial suture biology.⁵

Operative procedures to treat craniosynostosis are usually carried out during the first year of life. There are many different operative techniques employed around the world, and techniques continue to evolve. Early surgical procedures included the commonly performed linear craniectomy which was thought to release the normal growth of the underlying brain and allow perpendicular expansion of the skull. Experience has shown that this did not occur and that the surgically created suture rapidly closed. Later experiments with the interposition of a polyethylene

film⁶ were equally disappointing. Occasionally, such an operation could be successful if performed during the first months after birth with mild or incomplete craniosynostosis. Later cranioplasty techniques achieved better, more consistent results by more extensive operations using combinations of static and dynamic techniques. Whilst more successful, these operations carry a much higher risk of complications, longer hospital stays, and increased need for blood transfusion. In the last decade, however, there has been a renewed interest in minimizing procedures, and techniques using springs,⁷ distraction,⁸ helmets, and endoscopy⁹ are being employed.

Sagittal synostosis

The most common craniosynostosis is sagittal synostosis. The deficient growth results in a long and narrow skull, with the skull forming the shape of a boat keel or "scapha" when viewed from above (scaphocephaly) (Fig. 49a.1). Different patients may be more or less affected, from a slight elongation and a ridge of the suture to a severely deformed skull with frontal bossing, hypertelorism, and a long and pointed occiput.¹⁰ Surgery of sagittal synostosis might be a strip craniectomy during the first months or widening and shortening of the skull with a cranioplasty (Fig. 49a.1).¹¹ Results of a suture release can be enhanced using spring techniques.⁷ Most authors believe better results occur through early intervention, which of course is dependent on an early recognition, diagnosis, and patient referral¹² in the first months of the child's life.

Metopic synostosis

Synostosis of the metopic suture gives a pointed and narrow forehead and a compensatory widening of the back of the head. The closed suture is ridged and the skull looks triangular from the top, leading to the descriptive name trigonocephaly. A narrow distance between the eyes (hypotelorism) and epicanthal folds may be seen. The incidence is 1/15000 live births with a male predominance.¹³ There is also a concern regarding cognitive impairment in this population.^{14,15} The surgical approach is to make a rounder and wider forehead, increase intracranial volume anteriorly, as well as to reposition the orbits (Fig. 49a.2). The hypotelorism may be further improved or normalized by the use of springs.¹⁶

Unicoronal synostosis

Unicoronal synostosis or frontal plagiocephaly may be either left- or right-sided. The facial midline will deviate. The forehead on the affected side does not grow normally and stays flat. The orbital rim is dislocated upwards and backwards. On the opposite side the forehead has a compensatory bossing and the orbital roof is pushed downwards.¹⁷ If untreated, the

fronto-orbital dysmorphology will worsen with time. The suture is sometimes palpable as a ridge and the anterior fontanel is triangular,¹⁸ with the base on the affected side. Surgical correction aims at correcting the asymmetry of the frontal bone and superior orbital ridges (Fig. 49a.3).^{19,20} Ocular strabismus is common with unicoronal synostosis.²¹

Bicoronal synostosis

When both coronal sutures fuse prematurely, the skull cannot grow normally in the sagittal direction. The shape of the skull will be wide, short, and tall (brachycephaly) (see Fig. 49a.6). The forehead will show an upper bossing and the orbits are shallow with a repositioned supraorbital bar.²² Bicoronal synostosis may be an isolated disorder, but is sometimes a part of a craniofacial dysostosis syndrome. The suture may be an easy palpable ridge. In addition to the obvious skull shape appearance, X-ray examination shows an upwards displacement of the greater sphenoid wings bilaterally in the frontal projection. Surgery will aim at normalizing the shape of the forehead, reducing height and width of the skull, and allowing anterior–posterior elongation. This has been done using different techniques, such as the “floating forehead”, static or dynamic cranioplasty.^{23–25}

Lambdoid synostosis

Lambdoid synostosis is a rare form of craniosynostosis. It can affect one or both sides. If bilateral, the condition may seriously affect the intracranial space. In unilateral lambdoid synostosis the affected side of the occiput is flat with an ipsilateral occipitomastoid bossing and a contralateral parietal and frontal bossing. The skull shape looks like a trapezium both from above and behind.²⁶ The skull base on the affected side will assume a lower position compared to the unaffected side as visible on X-ray examination. The overall deformity of the skull resulting from untreated premature lambdoid synostosis is significant. Surgery will restore volume and convexity on the affected side.²⁷

Positional plagiocephaly

Positional plagiocephaly refers to the condition where a plagiocephaly is not associated with a premature craniosynostosis. Positional plagiocephaly is caused by external pressure on the soft infant skull. This may be a result of a sustained unbalanced position of the infant’s head. It is more common in premature infants due to the soft skull. A significant rise in positional deformities has been seen in the last decade due to supine positioning of children to prevent sudden infant death syndrome (SIDS). Since the recommendations of the “back to sleep” campaign a fortunate decrease in SIDS has been seen, however this has been accompanied by an increase in positional skull deformities. Infants who are placed in the supine position will sometimes lie on the same side of the back of the head. The occipital area will flatten on this side, further provoking the head to fall into the same position. If untreated, a compensatory bossing of the ipsilateral forehead will take place, further accentuating the deformity.²⁸ These conditions are treated by altering the positioning and by using a soft pillow.²⁹ The use of helmets may reverse the deformity more rapidly. The sooner the treatment is started the faster the recovery.³⁰ Surgery is best avoided in these children, with an exception for extreme cases not responding to conservative treatment. Prevention is the best treatment.

Craniofacial dysostosis syndromes

Craniosynostosis occurs as part of the craniodysostosis syndromes and commonly affects the cranial base and midface as well as the cranial vault. In addition to this restricted growth of the skull and the face, there are also different skeletal deformities and other organ malformations associated with these syndromes. There are more than 100 such syndromes described in the literature; most of them are very rare. They are of genetic origin, usually inherited as an autosomal dominant trait. Mutations are mostly found in the fibroblast growth factor receptor genes.³¹ Since there is no medical or genetic cure available yet,

Fig. 49a.3 (a) Unicoronal synostosis of the right side with flattening of the ipsilateral forehead. (b–d) CT scan shows a fused right-sided coronal suture with forehead and orbital asymmetry with a deviation of the metopic suture.

surgery provides the best treatment for these patients. A typical treatment plan will span over 20 years in most patients. The timing and choice of reconstructive procedures vary in different parts of the world, but the main indications for surgery are generally agreed upon.

Treatment in infancy

A child with a craniofacial dysostosis syndrome is often recognized at birth or shortly after due to the obvious clinical manifestations. Many craniofacial dysostosis syndromes result in deficient growth of midfacial structures, and the child's airway may have an increased resistance to airflow. As infants breathe through their nose obvious breathing difficulties will appear in these children leading to nocturnal apneas and snoring, and, if severe, hypoxia. Severely affected individuals may need a secured airway through a nasopharyngeal airway or a tracheostomy.

A restricted airway will also affect breast-feeding. Since the child cannot breathe normally through the nose, breast-feeding can be an impossible or difficult task for the child, resulting in feeding problems and failure to thrive. A nasogastric tube or a gastrostomy may solve these problems during this period, which can extend for years.

When cranial sutures are not patent, the brain may not have enough space for its rapid growth during the first year of life. This will lead to a raised intracranial pressure. If untreated, this raised pressure can cause behavioral and cognitive disturbances, deafness, blindness, or even death. Intracranial hypertension is a difficult diagnosis to make in this population. Invasive intracranial pressure (ICP) measurements can be made, but there are no defined limits of a harmful pressure in these children. A radiograph will reveal a "beaten-copper" appearance of the cranial vault. A CT scan may show similar bone deficiencies, and small or absent liquor cisterns. Ophthalmologic examination reveals a papillary edema of the optic nerve.³²

Accumulation of cerebrospinal fluid (CSF) within the cranium, hydrocephalus, is closely associated with craniofacial dysostosis syndrome patients. This is in contrast to non-syndromic, mono-sutural craniosynostosis, where it is rarely seen. The diagnosis of hydrocephalus is difficult, since a large number of craniofacial dysostosis patients will present with a ventriculomegaly that is not progressive and not shunt-dependent. In addition the hydrocephalus may be masked by a simultaneous craniostenosis causing a high intracranial pressure and small ventricles. The intracranial volume will be compromised by the craniostenosis at the same time as the hydrocephalus will try to expand the intracranial volume. Thus, repeated clinical follow-ups using magnetic resonance imaging (MRI) or CT scan and fundoscopy both before and after cranial surgery will be neces-

sary for a correct diagnosis of the shunt-dependent hydrocephalus.

The etiology of progressive hydrocephalus remains controversial. It may be the result of a constriction of the posterior fossa with a resulting increase in CSF outflow resistance. Another theory is that the venous outflow from the cranium is constricted leading to impaired CSF absorption.

Ventriculoperitoneal shunting is the treatment of choice. It is a surgical treatment with a not insignificant morbidity and should be reserved for those patients having a truly progressive hydrocephalus. These patients have to be monitored for over- or undershunting.

There are several kinds of visual impairment that affect craniofacial syndrome patients. Optic atrophy, amblyopia, corneal scarring, strabismus, and refractive disorders are common findings. Furthermore, malformations of brain tissue, eye, extraocular muscles, and orbit may occur in a wide spectrum. Optic atrophy with deteriorated vision or blindness can be present already at birth or will develop as a result of increased intracranial pressure. Fortunately, the surgical expansion of craniostenosis will release the pressure on the optic nerve and may hinder the progress of optic atrophy. In patients at risk of raised intracranial pressure, there is a need for repeated, careful ophthalmologic assessment using fundoscopy to detect a raise in intracranial pressure and prevent irreversible visual problems.

Amblyopia is a permanent loss of vision due to a suppressed eye that has not been stimulated due to a squint. Strabismus is common among these patients, and early treatment may restore binocular vision. Refractive problems are very common and need attention and correction with proper glasses.

When exorbitism is present in a child with shallow orbits, the eyelids sometimes cannot close properly, which may lead to corneal drying, ulcers, and scarring. The unprotected eye may also be damaged by trauma. In severe cases the eye may dislocate anteriorly requiring emergency repositioning and tarsorrhaphy.

Crouzon syndrome

The cranial and upper facial features of Crouzon syndrome are craniosynostosis, exorbitism, and a hypoplastic midface. The craniosynostosis is usually bicoronal, but may affect other sutures alone or in combinations (Fig. 49a.4).³³ Intracranial volume can be threatened by craniosynostosis, not allowing enough space for the growing brain. The exposed eyes will have a higher risk of becoming traumatized and dry out, and the resulting keratitis can cause scarring of the cornea and visual impairment. In addition, there is often a complex divergent strabismus.³⁴ Raised intracranial pressure and exposed eyes necessitate early intervention to gain intracranial volume, reshape the skull, and protect the eyes.

Fig. 49a.4 (a–c) Crouzon syndrome with brachycephaly but mild midface hypoplasia in a boy at 2 months of age, preoperatively. (d–f) CT scan showing extreme cranio stenosis with the brain growing through the cranial bones. (g–i) The same boy at postoperative follow-up after cranial expansion, here at 1 year of age.

Cranial vault surgery is performed during the patient's first year. The author prefers an early intervention when the child is about 4–6 months old. The reasons to perform early surgery are that the bone is more pliable, secondary deformities will be less, and the use of springs to enhance results will be possible.⁷ Other authors prefer to wait until 9–10 months of age to possibly lessen the need for repeat early cranial vault surgery. The surgery is performed by the standard coronal zigzag incision. Fronto-orbital advancement and reshaping is done, with narrowing of the broad skull shape. Particular attention is paid to the supraorbital complex, which usually has a concave deformity. This maneuver will also add some protection to the eyes. The occiput may simultaneously be advanced backwards either statically or by the use of springs. In some patients additional surgery such as ventriculoperitoneal shunting for hydrocephalus, lateral tarsorrhaphies, or repeat cranial expansion may be necessary.

During childhood the Crouzon patient will suffer from the effects of midface hypoplasia, including a compromised airway (sleep apnea), exposed eyes, speech difficulties, or from psychosocial problems relating to their distinctive appearance. Planning corrective surgery for this in childhood is controversial and many authors try to delay interventions for as long as the child and parents will allow. Facial growth will inevitably suffer from surgery, and while short-

term amazing results can be achieved these tend to relapse and disappear completely when the rest of the child grows into adolescence. This is something to be aware of when performing extensive surgery during childhood in Crouzon and other craniofacial dysostosis patients. The surgeon planning any intervention must be looking after the child and family as a whole and be thinking 20 years into the future, with each intervention building on the last. There is no plan that will apply to all patients, and the craniofacial surgeon must always consider the individual and their family, with his or her unique dysmorphology, and make a treatment plan that will best fit their needs.

Surgical treatment of the midface hypoplasia may be performed by a Le Fort III osteotomy, a monobloc osteotomy, a facial bipartition, or other combinations of osteotomies. Distraction osteogenesis techniques are used to bring bone segments further than with the use of traditional static techniques.³⁵ Long-term results have shown that despite surgery, relapse in adolescence may require additional or repeated procedures to achieve a satisfactory outcome (Fig. 49a.5). Growth of facial structures appears to be inhibited as part of the underlying syndrome, and surgery during childhood may negatively affect the remaining growth potential making these patients prone to relapse. The placement of long-term, indwelling, osteodistraction springs has been tried to prevent relapse following Le Fort III osteotomy.⁷

Fig. 49a.5 (a–c) Severe form of Crouzon syndrome at 5 years of age, still requiring a tracheostomy to be able to breathe. (d–f) Three-dimensional CT scan showing midface hypoplasia. (g–i) 3 years later after monobloc advancement, the child is no longer in need of a tracheostomy but there is still hypoplasia of the midface.

The final reconstruction of the Crouzon patient has to be done after skeletal maturity. The patient usually presents with shallow orbits, midface hypoplasia, and a class III malocclusion. It is not advisable to try to correct all deformities in a one-stage procedure. Orbital surgery or Le Fort III surgery is better performed as a first stage, and when the effect of that operation is stable a final orthognathic surgery is done. The author's preferred method is to address the shallow orbits by advancement and rotation of the entire orbital frames; infraorbital rims are advanced more than the supraorbital ones. This "spectacles-plasty" is an alternative to a Le Fort III or monobloc procedure.³⁶ When stable results are achieved and orthodontic treatment done the orthognathic surgery is performed.

Besides the more extensive surgery described, several minor surgical corrections may be useful for an esthetically pleasing result. Lateral canthopexies, rhinoplasty, genioplasty, contouring of bone irregularities, and fat grafting are a few examples of operations that can enhance the final result.

Pfeiffer syndrome

In Pfeiffer syndrome the presence of cranial vault malformation and midface hypoplasia is accompa-

nied by broad and deviated thumbs and great toes.³⁷ Incomplete syndactyly may be present. Three types of Pfeiffer syndrome have been described.³⁸ In type I there are brachycephaly, midface hypoplasia, and finger and toe abnormalities associated with a good prognosis and normal intelligence. Type II will have pansynostosis of the skull (cloverleaf skull), severe exorbitism, hydrocephalus, and brain dysfunction. There is a high incidence of early death. In type III the cloverleaf skull is not present, but a combination of cranial suture synostosis, exorbitism, often hydrocephalus, and brain dysfunction will also lead to a poor outcome in many cases. The cause is mutations in the FGFR 1 and 2 genes. The condition is of autosomal dominant inheritance, affecting about 1 in 100 000 births.

The craniofacial surgeon will approach the treatment of the skull deformity according to the different synostoses found, and the surgeries often have to be repeated. When hydrocephalus is present, ventriculoperitoneal shunting is carried out. Midface advancement is timed when necessary for breathing, eating, eye exposure, or psychosocial reasons. Orthognathic surgery and final cosmetic procedures are postponed until the late teens. Because the phenotype of each patient is different, an individual treatment plan is always needed.

Apert syndrome

Apert syndrome or acrocephalosyndactyly type 1 is a rare syndrome characterized by brachycephaly, hypertelorism, slanting palpebral fissures, strabismus, midface hypoplasia, and complex syndactyly of hands and feet (Fig. 49a.6). There are two main mutations of the fibroblast growth factor receptor 2 with the resulting differences in phenotypes. Both are autosomal dominant transmitted. Syndactyly is present in digits and toes 2–4 or all fingers and toes, accompanied by restricted movements of joints such as elbows and shoulders. Cleft palate is seen in less than half of the patients. Learning difficulties of varying degrees are associated with this syndrome. In adolescence, the Apert patient often suffers severe acne and hyperhidrosis.

The brachycephaly present has been seen as a result of a bicoronal synostosis. Studies have, however, revealed a much more complex dysmorphology with a combined dysplasia of the cranial base and vault.

The craniofacial surgery treatment starts during the patient's first year.³⁹ The brachycephalic head shape can be improved by cranial vault remodeling. This is done using fronto-orbital advancement techniques,⁴⁰ the back of the head may also be advanced posteriorly to further normalize the sagittal length of the skull.²⁵ Upward growth of the skull may be surgically restricted. The author's preferred method is to address all this by fronto-orbital advancement and reshaping, parasagittal strip craniectomies and suturing, and finally posterior advancement of the back of

Fig. 49a.6 (a–c) Apert syndrome with brachycephaly and midface hypoplasia in a boy at 2 months of age. (d–g) Hands and feet with multiple syndactylies. (h–j) CT scan showing wide open fontanelles and sagittal suture, closed bicoronal sutures, and occipitoparietal beaten-copper appearance of the bone caused by pressure from the brain. (k–m) Same boy at postoperative follow-up after cranioplasty at age 1 year.

the head using springs. Cleft palate is repaired at 6 months, but can be postponed if breathing difficulties are present. Hand reconstruction is carried out before the end of the first year, aiming to achieve opposition of the thumb and an effective grip by the time the child is beginning to explore their surrounds with their hands. Foot problems may often require surgical intervention, but could be postponed until before the child starts to walk.

During childhood, as in Crouzon syndrome, breathing difficulties, eating problems, eye exposure, or major psychosocial problems may occur and lead to surgical intervention such as midface advancement and/or facial bipartition. Again, the results of childhood surgery do not often last and typically surgery has to be repeated later. Visual and hearing impairment often occur and need attention.

In adolescence, orthodontic treatment will precede orthognathic surgery as described in Chapter 49b. Forehead contouring will be needed in a significant number of patients to refine the shape of the forehead. Orbital surgery for exorbitism or hypertelorism is performed in selected cases. Cheek augmentation, rhinoplasty, and eyelid surgery are adjunctive procedures for a better end result. Medical treatment for

the severe acne in these patients is also important to avoid scarring.

Saethre–Chotzen syndrome

Saethre–Chotzen syndrome is an autosomal dominant syndrome associated with the TWIST genetic mutation, characterized by brachycephaly with uni- or bicoronal synostosis, depressed nasal bridge, low hairline, low set ears with prominent crurae, and S-shaped upper eyelid ptosis (Fig. 49a.7).⁴¹ Learning difficulties may be present. Patients have a partial syndactyly between the second and third fingers and toes. Skeletal deformities are frequent. The incidence is about 1 in 25 000–50 000,⁴² but the expression of the phenotype is quite variable.

The surgical treatment of Saethre–Chotzen syndrome will require cranial remodeling according to the individual deformity, as described for other craniosynostoses. The eyelid ptosis is corrected. Sometimes a nasal correction, lateral canthopexy, or division of syndactyly will help in normalizing the appearance of this syndrome. Hearing loss, visual impairment, and seizures will also need attention when present.⁴³

Carpenter syndrome

First described by Carpenter in 1901, Carpenter syndrome or acrocephalopolysyndactyly type II, is a rare autosomal recessive genetic disorder of the RAB23 gene,⁴⁴ characterized by premature closure of cranial sutures.⁴⁵ Affected individuals have a pointed head (acrocephaly) or a broad and wide one (brachycephaly). Craniosynostosis may affect the sagittal, coronal, and lambdoid sutures, and is often asymmetrical. Cerebral malformation may occur and there is a high risk for learning difficulties.⁴⁶ Facial malformations may include midface hypoplasia, malocclusion, down-slanting palpebral fissures, a flat nasal bridge, and dysplastic low-set ears. Fingers and toes are short, webbed, or fused, and there may be supernumerary ones (polydactyly). Other physical abnormalities may occur, such as congenital heart defects, umbilical hernia, cryptorchidism, or short stature.

Craniofacial surgical treatment aims at correcting the different malformations in the calvarium (craniosynostosis correction),⁴⁷ midface (hypoplasia and occlusive malformations), and eyelids.

Muenke syndrome

Muenke described 61 individuals affected by coronal craniosynostosis associated with a Pro250Arg mutation in the FGFR3 gene.⁴⁸ The phenotype shows a great variability in this population. Both uni- and bicoronal synostosis are seen (Fig. 49a.8).⁴⁹ Different skeletal abnormalities of the hands and feet have been reported, such as thimble-like middle phalanges, coned epiphyses, and carpal and tarsal fusions. These latter findings are subtle and of no functional relevance. A partial sensorineural hearing loss is common. Learning difficulties may be present in some cases.⁵⁰

Surgical results may be less rewarding in this population when compared to uni- or bicoronal craniosynostosis patients without this mutation, and repeated surgery is more often necessary.⁵¹

Treacher Collins syndrome

The above-mentioned syndromes are all characterized by craniosynostosis. This is not the case in

Fig. 49a.8 (a–c) A 5-year-old boy with Muenke syndrome and a deformed head shape. (d–f) Three-dimensional CT scan shows bicoronal synostosis.

Fig 49a.9 (a–c) Treacher Collins syndrome in a patient referred for additional reconstruction at 58 years of age, who has experienced return of the deformity by aging.

Treacher Collins syndrome (TCS), but it deserves mention due to the large amount of corrective craniofacial surgery that is required. The TCS patient has hypoplasia of facial structures with a convex profile of the face. The face will show downward slanting of the palpebral fissures, colobomata of the lower eyelids, hypoplasia of especially the zygoma and mandible, malformation of the external ear, middle ear malformation with hearing loss, malocclusion, abnormal hairline, and cleft palate (Fig. 49a.9).⁵²

Severely affected individuals will have a compromised airway at birth requiring a live-saving tracheostomy. The main reason for this is usually attributed to a severely retruded mandible, but the root cause may be much more complex. Closure of a cleft palate will have to be carefully planned and timed because of possible effects on the airway. Orthognathic surgery will be thoroughly addressed in Chapter 49b, so this text will focus on the other surgical areas involved.

The reconstruction of the external ear is a staged procedure using rib grafts and soft tissue coverage by different techniques as described by Brent and Nagata,^{53,54} or by a bone-anchored prosthesis. In a few cases, the middle ear deformities may be surgically correctable, but more often a bone-conducting hearing aid will be the solution for hearing improvement.

Nasal reconstruction will improve the broad nose, the dorsal hump, and loss of tip projection through a traditional rhinoplasty. Nasal surgery is done after completion of orthognathic procedures.

The lower lid coloboma and slanting palpebral fissures are difficult problems that are very hard to correct. Flaps from the upper eyelid, Z-plasties, skin transplants, and other methods have been tried with varying success.⁵⁵

Reconstruction of the zygoma deformity and lengthening of the lateral orbital wall can be achieved by a bicoronal incision using split calvarial bone grafts.⁵⁶ Lateral canthopexies are performed simultaneously.

Finally, additional soft tissue augmentation of the temporal fossa, periorbital area, or cheeks can be done using a dermal fat graft, fat transfer, or free tissue transfer.

Chapter 49b

Craniofacial Syndrome Patients – Orthognathic Surgery

Karl-Erik Kahnberg

The maxillofacial region is often affected in craniofacial syndrome patients. Treatment plans for these patients are made by the craniofacial team of specialists. Reconstruction of the maxillofacial region is most often performed after cessation of growth, although in urgent cases earlier treatment can be done. Orthognathic surgical techniques are very useful to correct malocclusion and malformations of the face. The most commonly appearing syndromes with severe effects on the maxillomandibular region are Crouzon syndrome, Apert syndrome, and Treacher Collins syndrome. Hemifacial microsomia is another developmental craniofacial disorder, which presents most frequently in a unilateral form but can also appear bilaterally. The diagnosis, treatment plan, and surgery to correct facial asymmetry in these patients are discussed in the chapter.

Crouzon syndrome

This syndrome was first described by a French neurosurgeon in 1912. The characteristic presentation of the syndrome includes exorbitism and retrognathic max-

illary complex together with craniosynostosis. The frequency reported in the literature is about 1 case in 25000 births. The craniosynostosis usually affects both sides of the coronal sutures. This bilateral pattern gives a symmetrical appearance with a reduced anterior cranial fossa. Due to the shallow orbits, exorbitism is common and in some cases hypertelorism is also seen (Fig. 49b.1).^{1–5}

The genetic pattern is autosomal dominant inheritance. The syndrome is usually caused by mutations and newly formed gene expressions.⁶ In Crouzon syndrome the genes involved in development of osseous tissue are altered. Fifty percent of cases are spontaneous mutations and the rest are inherited. If one of the parent's genes are defective this is usually enough to transfer the disease. Although the expression of the disease may be very mild transferring the disease to a child is still a big risk.

The routine treatment in craniosynostosis patients is initial surgical treatment of the cranial bones as described in the Chapter 49a.

Maxillofacial characteristics

These patients usually have a small maxilla with a high palate and, to various extents, a constricted dental arch. Crowding of teeth is frequent but to a varying degree.⁷ Due to the maxillary hypoplasia the mandible looks prognathic, although cephalometrically it may be retrognathic. The difference in size between the maxillary and the mandibular dental arches will frequently cause a bilateral crossbite. The mental status in these patients is usually normal.

Orthodontic treatment

Orthodontic treatment usually begins 2–3 years before the orthognathic surgery. In demanding cases, however, with extreme crowding of the teeth in combination with a constricted upper dental arch, the orthodontic treatment may start earlier. A combined approach by orthodontists and maxillofacial surgeons will decide on the most suitable timing. Usually

Fig. 49b.1 (a) Patient with Crouzon syndrome after craniostylosis operation and orbital frame surgery. (b) The patient in lateral projection. (c) Lateral radiograph showing open bite, maxillary retrognathia, and tilted position of the mandible. (d) The occlusal situation. (e) Frontal view of the patient after bimaxillary surgery and genioplasty. (f) The patient in profile view. (g) Lateral radiograph of the patient 2.5 years postoperatively. (h) Occlusal situation 2.5 years after orthognathic surgery.

it is advisable to postpone the orthognathic surgery until the age of 16–18 years, with verified growth cessation demonstrated by radiographs of the hand showing growth plate closure.

The orthodontic treatment will vary in length depending on the dental occlusal situation and crowding of the teeth. The presurgical orthodontic treatment normally includes decompensation of teeth and lining of the dental arches. The treatment is always by fixed appliances and can take from 1.5–2.5 years to accomplish. Ideally the dental arches should be fitting optimally, preferably in a class I relation after surgical movements. If there are special psychological aspects involved the treatment can start earlier and surgery can also be performed earlier. The risk with an early interference is, of course, that continued growth will disturb the surgical–orthodontic result and a second operation will be needed later on.

Orthognathic surgery

The degree of maxillofacial deformity may also have an impact on the timing of surgical treatment, although it is usually advisable to postpone surgery until growth cessation. Depending on the degree of midfacial retrognathia, distraction osteogenesis can be the method of choice in demanding cases. Due to the varying expression of the syndrome it is difficult to make a routine analysis using standard cephalometric values. Every case has to be individually anal-

ysed and planned according to the clinical appearance and with regard to the orthognathic surgical methods available today.

In Crouzon syndrome there is a variation from very mild cases to very severe malformations, with the usual features being a small maxilla with a retrognathic position and a mandible of a normal size and in an orthognathic position, or sometimes also somewhat retrognathic. The chin point frequently has a flat appearance. The retrognathic position of the maxilla affects the whole midface although the base of the nose is in a normal position in relation to the infraorbital margins. If there is a pronounced exophthalmus, advancement of the infraorbital and supraorbital rims may be needed, with a so-called orbital frame operation (see Chapter 49a). When the midfacial retrognathia also affects the infraorbital margins and the base of the nose there is an indication for Le Fort III surgery with advancement of the midface, including the infraorbital margins, part of the zygoma, the base of the nose, and the maxillary complex. However, with the maxillary Le Fort III operation it is very difficult, not to say impossible, to advance the structures in a horizontal plane; it most likely becomes a rotation of the complex and it is impossible to correct the discrepancies between the upper and lower jaws. A combination of Le Fort III and Le Fort I in severe cases can be the solution of choice. Due to the relatively high risk for complications with the Le Fort III surgery an alternative is to do an orbital frame operation,

Fig. 49b.2 (a) Young male patient with Crouzon syndrome. Severe retrognathic position of the maxilla combined with a retrognathic mandible. (b) Occlusal situation after presurgical orthodontic treatment. (c) Lateral radiograph preoperatively. (d) Lateral view after surgical correction with large anterior movement of the maxilla and genioplasty. (e) Lateral radiograph postoperatively. Maxillary advancement of about 15mm. and at a later stage continue with a Le Fort I osteotomy when the results of the orbital frame operations are clearly visible. The shallow bony orbits usually found in Crouzon syndrome patients limit the degree of orbital frame augmentation but it is still helpful in many patients.

The Le Fort I surgery, usually 6 months after the orbital frame operation, is carried out just below the infraorbital nerve and often extends into the malar process in order to increase midfacial projection. Since the maxilla mostly is smaller than the mandible, regeneration of the maxilla with widening of the dental arch is indicated (Figs 49b.2–49b.4). If the mandible has a cephalometrically and clinically acceptable sagittal position, the maxilla is advanced the whole distance to achieve a satisfying occlusal locking. If necessary chin advancement can be performed at the same time as the maxillary advancement. The desired direction of the chin advancement can easily be achieved by angling the sliding genioplasty to meet the esthetic demands. Even with extensive maxillo-facial advancements the postsurgical skeletal stability is satisfying. It is of utmost importance to achieve surgical advancement with the final position being a relaxed position without tension in the surrounding soft tissue (Figs 49b.1 and 49b.5).

Apert syndrome

Apert syndrome, also named acrocephalosyndactyly, was first described in 1906. A neurologist from France noticed these patients with certain characteristic signs including craniosynostosis, midfacial hypoplasia, and syndactylism of the hands and feet. The occurrence of the syndrome is about 1 case in 100 000 births. There is an autosomal dominant inheritance pattern in these patients. The coronal sutures are bilaterally affected with synostosis and a compressed anterior cranial fossa. The forehead is high, flat, and dominating (Fig. 49b.6).^{1–3,6} Due to disturbed development of the metopic and sagittal sutures the patient's head develops a bulging appearance. Hyperthyroidism and exorbitism are frequently involved in the syndrome.

Apert syndrome is a collection of malformations of the cranium and also the facial bones, hands, and feet. Furthermore, there are skeletal malformations, such as limited joint movements, balance difficulties, breathing problems, audiovisual problems, as well as problems with swallowing, speech, and chewing. Learning difficulties are frequently present. In 98% of patients with Apert syndrome there is a new mutation in the FFR-2 receptor gene in chromosome 10.

Fig. 49b.5 Clinical surgical view of six-piece segmentation of the maxilla.

Fig. 49b.6 Surgical segmentation of the maxilla to enable transverse widening of the maxilla in seven pieces including osteotomy between central incisors.

The disease is inherited in an autosomal dominant pattern. However, there is a large variation in the degree of malformation between different patients (Fig. 49b.7).⁸

Maxillofacial characteristics

Apert syndrome patients have mostly a typical facial appearance with a rectangular-shaped head and a prominent lower face portion. The mandible is often prominent and cephalometrically prognathic while the midface is retruded and retrognathic in clinical and cephalometric aspects. The nose is frequently malformed and bulging, and in severe cases very

Fig. 49b.7 Schematic illustration of the segmentation procedure.

retruded with the nasal bone posterior to the glabella region.⁹

There is often difference in size between the upper and lower jaw, the maxilla being smaller and with a collapsed dental arch with a high positioned palate. The incidence of an open or submucous cleft palate is around 30%.⁷

The maxillary tuberosities are often hyperplastic and extend over the palate. Crowding of teeth is especially remarkable in the maxilla but often also occurs in the mandible. Cephalometrically and clinically there is a class III malocclusion, mostly in connection with an anterior open bite. The mandible can be truly prognathic but in many cases there is a pseudoprognathic situation due to the hypoplastic maxilla.

Orthodontic treatment

Apert syndrome patients need extensive orthodontic treatment before any orthognathic procedure can be carried out. As with all other orthognathic surgical patients, the ideal timing for surgery is after cessation of growth, normally when they are 16–18 years old. Growth indications, as shown in the hand radiographs with phalange closures, will decide the suitable time. However, as in Crouzon syndrome patients and all other severely malformed patients, earlier interference may be needed due to psychological indications.

Planning of surgery involves the surgeon and the orthodontist. Orthodontic treatment presurgically includes necessary extractions, lining of the dental arches, and decompensation if necessary. If the curve of Spee is unfavorable, segmentation of the orthodontic appliances can be chosen. The presurgical orthodontic treatment may last 1.5–2.5 years prior to the surgical treatment.

Orthognathic surgery

The most frequent orthognathic surgical approach to patients with Apert syndrome is a bimaxillary procedure with advancement of the maxilla through

a high level maxillary Le Fort I osteotomy combined with a setback of the mandible using a sagittal split operation.

In addition to the mandible being prognathic or pseudoprognathic there may be an unfavorable inclination of the anterior alveolar process with protrusion of the lower lip accentuating the prognathic appearance. In these cases it is advisable to add a segmental osteotomy procedure to the sagittal split. In many cases a chin plasty is also performed, either by sliding osteotomy or by use of chin implant material.

In the most severe cases, with retrusion of the maxilla and midface and also of the infraorbital margins and the nose, it is not possible to reconstruct the patient with a Le Fort I osteotomy; a Le Fort II surgical procedure is required, also involving part of the infraorbital margin and the base of the nose in order to achieve an adequate reconstruction. The Le Fort II procedure is difficult to advance manually to the extent that is needed; in these cases the advantage of distraction osteogenesis is clearly seen.

Distraction osteogenesis is achieved by use of a head frame and plates which are placed strategically in the maxilla, two on each side, one of them lateral to the nose and one in the infraorbital region. Wires are then attached to the plates and transferred through the soft tissue to the anterior part of the head frame allowing for a parallel distraction. The direction of distraction is of utmost importance to achieve an acceptable result. The distraction device will move the maxillary complex about 1 mm/day until a maximum of 30 mm is achieved. There is then a consolidation period of about 8 weeks. It is still difficult to obtain a good final result using only distraction in these cases.

In the end conventional orthognathic surgery has to be performed to get the best final result. The distraction procedure can begin at an early age aiming for an intermediate anterior positioning of the maxillary complex which will facilitate the final surgical procedure.

Normally, however, a bimaxillary orthognathic procedure is enough to get a satisfying result for dentofacial correction. Additional rhinoplasty and soft tissue augmentation as well as correction of irregularities in the forehead may be indicated (Figs 49b.6 and 49b.7).

Pfeiffer syndrome

This syndrome is similar to Apert syndrome. It was first described in 1964 and involves craniostosis like Apert syndrome. Characteristic features are very broad thumbs and broad great toes, and syndactyly of the hands is also sometimes seen. As in Apert syndrome there is an autosomal dominant inheritance pattern. The other craniofacial features are the same as for the Apert patients. However the degree of craniofacial disfiguration and the syndactyly in

Pfeiffer syndrome are milder and not so pronounced. These patients have normal mental development.

Saetre–Chotzen syndrome

Saetre–Chotzen syndrome was described in 1931. These patients have a similarity to Apert patients, although there is a marked facial asymmetry in Saetre–Chotzen patients.¹⁰ The symptoms include craniosynostosis, a low-set hair line, eyelid ptosis, partial syndactyly of the hands, and facial asymmetry. The syndrome has an autosomal dominant inheritance pattern like Apert syndrome. The synostosis affects the coronal suture bilaterally but in an asymmetric way which results in a plagiocephalic facial expression. The mental capacity in these patients is usually normal.

Treacher Collins syndrome

This syndrome is also called mandibulofacial dysostosis or Franceschetti–Klein syndrome and was first described in 1846.¹¹ Edward Treacher Collins reported on two cases in 1900.¹²

Treacher Collins syndrome is equally distributed among males and females. The incidence is about one in 10 000 births. Mild variations of the syndrome may not show up in statistics so the incidence rate is probably higher. The syndrome may vary quite a lot in expression.^{13–15} The cause of the disease is chromosomal changes due to mutation in chromosome 5 within q31–q33. Other genes are also affected, such as TCOF1, MSX2, FRABP, PRR1, and PRR2. The damage to the genes causes disturbances in the neural crest cells. In 50% of cases, the syndrome is a dominant inherited disease. In the remaining 50%, spontaneous mutations could be the underlying factor. The facial region and mouth develop from the first and second branchial arches. The ectomesenchyme from the neural crest is responsible for the development of cartilaginous, osseous, dental, and soft tissue structures of the facial skeleton. The disease also affects breathing due to constricted airways as well as external and internal ear, the zygoma arches, the eyes, the nose, and the jaws.¹⁶ The ear problems are both a hearing problem and an esthetic problem. These problems are handled by plastic surgeons and ENT doctors.

Maxillofacial characteristics

Treacher Collins syndrome patients have a very special appearance due to the abnormal anatomy of the mandible, the absence of zygoma, the slanting eyes, and disfiguration or loss of external ears. The mandible has a typical appearance with a short ascending ramus and a short mandibular body length. A typical finding in Treacher Collins syndrome is a concave antegonial notch of the mandibular angle. This curved

anatomy of the mandibular body together with the dental arch will, of course, give an unfavorable appearance of the curve of Spee.

The mandible is also retruded and retrognathic due to the short ramus length. Patients present with an open-bite deformity of varying magnitude. The mandible, although hypoplastic, normally contains all the essential structures. However, the condyle may be deformed or hypoplastic (Figs 49b.8 and 49b.9). The maxilla is often prominent in comparison to the lower third of the face. Although nasal breathing is compromised, the external nose is large and sometimes disfigured.

The occlusion is mostly angle class II malocclusion with anterior open bite. The palatal plane is rotated upwards in the posterior part resulting in an incorrect angle to the S-N plane and also in constriction of the choanae.

The short lower third of the face results in a steep mandibular plane which also affects the occlusal plane; together the result will be an anterior open bite with an abnormal curve of Spee.

The hypoplastic maxilla and retrognathic mandible in connection with varying degrees of coronal stenosis can complicate the upper airway space. Tracheostomy is sometimes indicated.

Orthodontic treatment

The presurgical orthodontic treatment will be started 1.5–2 years prior to the surgical date. The upper jaw teeth may be aligned in a conventional way although the curve of Spee in the mandible makes it difficult to achieve alignment of the dental arch. Segmental orthodontics may be a solution, treating the anterior part as one segment and the posterior as one right and one left segment. If the maxilla is to be surgically segmented, the orthodontic treatment is also carried out in a segmented manner.

Orthognathic surgery

The orthognathic surgical approach to these patients is difficult and it is not easy to achieve normalization of the face.

The surgical approach can be made in different ways.^{17–19} With regard to lengthening of the short ramus, osteodistraction is a technique which will increase the length of the ramus and at the same time advance the mandibular body and to some extent close the open bite deformity. The distraction can be done either extraorally or with intraoral devices. However, due to the negative curve of Spee and the curvature of the mandibular body it is difficult to achieve an optimal final result with this technique. Even after distraction osteogenesis, conventional orthognathic surgery has to be performed in order to obtain a good final occlusal result.

Another orthognathic surgical approach in the mandible is mandibular body osteotomy between the

first and second premolars or between the second premolar and the first molar depending on the curvature of the mandibular body. This osteotomy can be made in combination with myotomy of the suprahyoidal muscles, i.e. geniohyoideus and musculus digastricus, but not, of course, the genioglossus. The myotomy is made to facilitate lifting of the anterior segment of the mandibular body and straightening the curve of Spee and closing the open bite.

The mandibular procedure is often combined with a maxillary osteotomy with impaction and, if necessary, widening of the maxilla. Occasionally it is necessary to make a set-back of the maxilla by use of a segmentalized technique and removal of two premolars. Additional genioplasty is indicated in most cases.

Orthognathic surgery is preferably done after skeletal maturation at between 15 and 18 years of age.

A variety of surgical methods has been recommended in these cases, including bilateral sagittal split, osteotomy, sliding genioplasty, maxillary osteotomy, segmental osteotomy, and L-shaped osteotomy of the ramus.

Maxillary osteotomy with multisegmentation of the maxilla may correct the transverse occlusal discrepancy and may also correct the vertical height of the maxilla. However, posterior repositioning of the maxilla may be difficult, although it would help to balance the sagittal relation between the jaws. Segmental maxillary osteotomy with bilateral extraction of a premolar may be a solution in some cases.

In the author's clinic another strategy has been proposed, focusing on the hypoplastic and abnormal curvature of the mandible. Although mandibular body osteotomy is seldom done today in maxillofacial clinics, it may be a method of choice in these patients. A mandibular body osteotomy is performed using a step osteotomy in the form of a Z bone incision through the mandibular body but maintaining all the soft tissue vascular supply; it is usually made between the first molar and second premolar, depending on the case. The step osteotomy is made between the roots of the teeth and then parallel to the mandibular base above the mental foramen. If necessary, nerve transposition can be carried out. Just anterior to the mental foramen the cut goes down to and through the base of the mandible. By doing this osteotomy bilaterally the curve of Spee can be changed to a more normal appearance and the anterior open bite can also be closed. The mandibular body osteotomy may need to be combined with myotomy of the suprahyoidal muscles so that the anterior segment can be rotated to the planned position. Cortical bone grafts are positioned in the spaces left in the osteotomy areas after rotation of the anterior part of the mandible. Fixation of the mandibular body segments is achieved by use of 2.5 mm plates. Sometimes a reconstruction plate with a larger caliber may be indicated depending on the size of the anterior open bite.

Fig. 49b.8 (a) Male patient with hemifacial microsomia preoperatively. (b) Frontal radiographic projection showing the facial asymmetry. (c) Preoperative occlusal view. (d) Frontal radiograph after surgical correction with bimaxillary osteotomy, genioplasty, and ramus augmentation. (e) Occlusal view after orthognathic surgery. (f) Clinical photograph 2.5 years after surgical orthodontic correction.

The mandibular body osteotomy can be combined with a sliding genioplasty in a direction to shorten the lower face region. The genioplasty can also be done as a second procedure after the mandible has healed for 6 months.

Maxillary osteotomy may or may not be necessary in these cases; it can correct the vertical position of the anterior teeth and correct some of the unfavorable anticlockwise rotation of the mandible.

With the above-mentioned orthognathic surgical methods it is possible to achieve an acceptable occlusion and functionally acceptable chewing. However, as has been described in the literature, Treacher Collins syndrome is one of the most challenging and difficult conditions to reconstruct. Despite numerous operations by a lot of specialists, optimal correction is impossible to achieve and patients still have the typical presentation of Treacher Collins syndrome. Although the symptoms associated with Treacher Collins syndrome are not easily removed, the patients

can still be functionally rehabilitated in a satisfactory way (Figs 49b.8 and 49b.9).

Augmentation and reconstruction of the zygoma region can be made either by use of autologous bone graft or implants of different kinds, like silicon or Teflon, or by use of lipid tissue graft. However, it is difficult to get a good long-term result in reshaping the contour of the zygomatic arches.

Attempts have been made for early surgical intervention by use of distraction osteogenesis in order to lengthen the ramus and improve the function and esthetics in childhood. However, no long-term results are yet available.

Other syndromes

Other more seldom appearing craniofacial syndromes like Moebius syndrome, Frazer syndrome, Klippel-Feil syndrome, Down syndrome, Goldenhar syn-

Fig. 49b.9 (a) Young male patient with Crouzon syndrome. Severe retrognathic position of the maxilla combined with a retrognathic mandible. drome with dentofacial deformities have to be individually planned and operated on with the orthognathic surgical arsenal available today.

Hemifacial microsomia

Introduction

Hemifacial microsomia presents with facial asymmetry of varying degrees depending on the severity of the disorder. This cranio-maxillofacial syndrome is an intrauterine defect affecting the branchial arch during pregnancy. The possible cause can be intrauterine bleeding or any kind of trauma and it is not an inherited disease. It most frequently affects only one side of the face and head but can occasionally present bilaterally. The expression of the syndrome is variable, depending on the severity of the deformity, from very mild with minor facial asymmetry and no effects on the ear, either external or internal, to very severe forms with loss of hearing, no external ear, no temporomandibular joint, and no mandibular ramus.^{20,21,22}

Maxillofacial characteristics

Depending on the degree of abnormality the surgical approach may vary considerably from total joint replacement and plastic surgical correction of the external ear to no surgery at all or just minor cosmetic corrections for very mild forms with all anatomical structures present.

The facial asymmetry also affects the maxilla; during the growth period it will adapt to the canted mandible and achieve a slanted position on the affected side. The occlusal plane will thus be more or less angulated horizontally towards the eye plane. In extreme cases the orbits may also be affected by the disturbed growth pattern and need surgical correction.

Orthodontic treatment

As always there is a team approach to these cases and the occlusal situation has to be evaluated before any surgical interference is made. Crowding of teeth and unfavorable inclination of the teeth are treated by lining of the dental arches and decompensation. Indicated extractions are carried out.

Orthognathic surgery

Bimaxillary surgery is indicated to level the maxilla and at the same time widen it if necessary in the transverse direction.

If the temporomandibular joint and ramus are missing, replacement will be made by costochondral rib graft and reconstruction of the fossa region with condroid tissue.^{21,23} The chondroid part of the rib

graft is trimmed and formed to act as the new joint. Part of the chondroid tissue on the rib can be used as fossa reconstruction material. The surgical procedure is preferably performed using an extraoral approach which facilitates the tissue handling.

Model surgery is necessary to get a wafer orienting the maxilla to the correct position in the vertical, horizontal, and transversal planes. Once the maxilla is positioned with miniplates and bone graft, preferably of cortical type, on the downtilted side, the mandibular osteotomy is performed and the rib graft attached.

The orthognathic surgical techniques used are the maxillary osteotomy with or without multisegmentation combined with sagittal split of the mandible, or, in special cases with a rudimentary ramus and angle of the mandible, an extraoral submandibular approach can be indicated to enable identification of the tiny anatomical structures (Fig. 49b.10).

In total joint and ramus replacement the surgical approach begins with the maxillary osteotomy to level and reposition the maxilla according to the cephalometric analysis and model surgery. Once the maxilla is positioned parallel to the eyes and in an acceptable position horizontally as well as transversely, the mandibular osteotomy can be started. It is of utmost importance that the vertical position of the maxilla achieves a normal relationship between the upper lip and frontal teeth. The upper jaw incisors should be visible 2–3 mm under a relaxed lip position. If necessary transverse widening of the maxilla can be done with the multisegmentation technique. The maxilla can also be rotated in order to get a slight augmentation on the affected side. A cortical bone graft is positioned in the gap between the maxilla and midface after repositioning of the jaw to prevent the maxilla from relapse.

It is not recommended to do both the maxilla and mandible at the same time because of the risk of getting disoriented (Fig. 49b.10).

For the costochondral rib graft reconstruction, a submandibular incision and a preauricular incision are made. After blunt dissection in the preauricular region a suitable fossa place is identified. The posterior part of the mandibular body is identified after blunt submandibular dissection.

Costochondral rib graft is obtained in a conventional manner (see Chapter 23) and the chondral part of the rib is modeled and shaped to be the new condyle. Chondral tissue from the rib can also be formed and modeled to be the fossa structure and attached to the planned fossa region to prevent ankylosis of the rib graft.

After maxillary repositioning and fixation with miniplates and the mandibular osteotomy is finalized on the non-affected side, the costochondral rib graft is placed in position after intermaxillary fixation and locking of the jaw.

The rib graft is attached to the mandibular body with plates and screws. Intermaxillary fixation is

Fig. 49b.10 (a) Male patient with Treacher Collins syndrome, frontal projection. (b) Lateral clinical view of the patient. (c) Occlusal situation with large open bite. (d) Lateral radiographic projection showing a large open bite and rotation of the mandible with the typical appearance for Treacher Collins syndrome. (h) Lateral radiograph 2.5 years after surgical correction.

maintained in these cases for 6 weeks. In cases with less severe abnormality, where there is still a functioning joint, bimaxillary procedures without joint replacement are carried out. Even if the ramus and joint are thin and tiny they may still function perfectly well.

Occlusal and functional correction can be achieved with the techniques mentioned. However, to improve the facial asymmetry both in the bony structures and the soft tissue, additional procedures like ramus implant, mandibular angle implant, and chin implants have to be carried out. The implants are available from manufacturers in different sizes. Bone graft material is not recommended due to the resorption tendency of bone graft without functional stimulation. Soft tissue augmentation using lipid tissue graft material can be done in indicated cases.

If the orbit is affected by the condition and has an abnormal position, an orbital frame operation with repositioning of the orbit may be indicated before all dentofacial reconstruction begins.

Bilateral microsomia cases, depending on the severity of the syndrome, have to be reconstructed with a bilateral costochondral rib graft if there is no functioning joint and ramus. If there are rudimentary joint structures with satisfactory function, bimaxillary procedures can be carried out with combination of maxillary osteotomy and bilateral ramus osteotomies. Additional augmentation procedures and genioplasty have to be performed to improve the facial contour.

Chapter 50

Reconstruction of Maxillary Defects

Nagi Demian, Joann Marruffo, James McCaul, and Mark Eu-Kien Wong

The chapter is an overview of treatment options for maxillary reconstruction. Classification of maxillary defects depends on the extent of the defect, regarding both the hard and soft tissue, and is the basis for the choice of which surgical technique to use. The treatment can vary from local flaps or pedicle flaps to a composite free tissue transfer with bone and a generous amount of soft tissue. Implant-supported overdentures seem to be the most predictable restoration but zygoma implants also have a place in the reconstruction of maxillary defects. Different flaps for use in surgical reconstruction are presented in detail.

Introduction

The maxilla occupies a central location in the facial skeleton unifying the orbits, zygomaticomaxillary complex, nasal unit, and stomatognathic complex into a single functional and esthetic unit.¹ The comprehensive reconstruction of maxillary defects following trauma or tumor-ablative surgery is a complex process requiring the collaborative efforts of different medical and dental specialists, skilled in restoring missing skeletal and soft tissues, a vascularized graft bed, and the reconstruction of dental and ocular structures. Wound characteristics and patient factors help determine the most appropriate management strategy and among the more salient considerations are defect size, type of missing tissue, ability to withstand prolonged surgery, availability of donor tissue, and the expertise of the management team. Other broader issues which must also be considered include cost of rehabilitation and patient prognosis, and these require evaluation of a complex array of social, professional, economic, and emotional factors.

Historically, and still in many centers, removable dental prostheses are felt to be superior to flaps or grafts for the reconstruction of maxillary defects. Prosthetic devices are capable of restoring missing skeletal, soft tissue, and dental elements in a single procedure and do not require multiple revision surgeries to achieve function and esthetic harmony with the remaining structures. Concerns over surveillance of the tumor site allowing prompt management of recurrent disease also mitigate in favor of a removable prosthesis, but, notably, this advantage has not been shown to influence survival after resection of squamous carcinoma or high-grade salivary cancer. Furthermore, the use of advanced imaging techniques such as magnetic resonance imaging (MRI) or positron emission tomography/computed tomography (PET/CT) and the ability to visualize remote or closed sites with flexible endoscopic procedures, provide sensitive and accurate means for postablation surveillance. In addition, refinements in vascularized tissue transfer techniques and advances in dental implant technology have addressed some of the limitations to

reconstruction of the maxilla with biological tissue, and have provided patients with significant speech, masticatory, and social benefits derived from permanent obturation of their maxillary defect.

Classification and treatment approaches for maxillary defects

Classification of maxillary defects

Numerous classification systems for maxillary defects have been proposed, including those by Ohngren (1933), Aramany (1978), Spiro (1997), Davison (1998), Brown (1996), Cordeiro (2000), and Okay (2001). The more recent classifications attempt to define the anatomical extent of each defect and provide recommendations for different reconstructive approaches, based on experience. Since traumatic defects do not follow surgical principles, their characteristics and efforts to classify them are random. In this chapter, two commonly used systems will be employed, one developed by Okay, a prosthodontist, and the other by Brown, a surgeon, as foundations for the discussion.

Okay classification

The classification system proposed by Okay takes into consideration both surgical and prosthetic tech-

niques for maxillary reconstruction. It addresses important reconstructive goals, such as closure of oronasal communications, the provision of a stable foundation for dental restoration, reconstruction of midface symmetry, and stabilization of orbital contents. This system divides maxillary defects into three categories based on the presence or absence of dental structures that can be used for the retention of prosthetic devices (Table 50.1).

Class Ia defects involve the hard palate, but not the tooth-bearing alveolus (Fig. 50.1). Defects of the maxilla and tooth-bearing areas posterior to the

Fig. 50.1 Okay class Ia: defect resulting from previous biopsy attempt.

Table 50.1 Okay classification of maxillary defects.

Classification	Anatomy	Surgical reconstruction	Prosthetic reconstruction	
Ia	Involves hard palate but not tooth-bearing alveolus	Soft tissue graft	Maxillary obturator	
Ib	Involves any portion of the maxilla posterior to the canines or the premaxilla	Soft tissue graft	Maxillary obturator	
II	Involves any portion of the tooth-bearing maxilla but only one canine, or transverse palatotomy less than 50% of the palate	Vascularized bone-containing free flap	Maxillary obturator	
III	Involves any portion of the tooth-bearing maxillary alveolus, includes palatotomy that involves more than half of the palate surface	Vascularized bone-containing free flap	Implant-supported prosthesis	

canines, or isolated defects of the premaxilla are classified as class Ib (Fig. 50.2). A class II defect involves up to half the maxilla including the alveolus and premaxilla and includes the ipsilateral canine if present (Fig. 50.3). Anterior transverse palatotomy defects measuring less than one half of the palatal surface are included in class II. Class III defects are more extensive and involve more than half of the maxilla, the associated alveolar bone, and both canines. Total palatotomy defects and anterior transverse palatotomy defects involving more than half of the palate are classified as class III defects (Fig. 50.4). Subclass F defects involve the inferior orbital rim, and defects that involve the body of the zygoma are in the subclass Z.²

Brown classification

This system considers the involvement of structures in both vertical and horizontal planes to classify different maxillary defects.³ It begins with identification of the vertical defect (class 1–4) followed by description of the horizontal extent (A, B, C), representing absent midline structures such as the nasal septum and the contralateral maxilla (Table 50.2). This system provides a means to assess the most likely functional outcome for a patient and, like the Okay classifica-

tion, outlines the reconstructive requirements for each type of defect.

Vertical components are classified as:

- Class 1: maxillectomy with no oro-antral fistula. Class 1 defects involve the hard palate, but not the tooth-bearing alveolus (Fig. 50.1).
- Class 2: low maxillectomy.
- Class 3: high maxillectomy.
- Class 4: radical maxillectomy.

Horizontal components are classified as:

- A: unilateral alveolar maxilla and hard palate resected. Less than or equal to half the alveolar and hard palate resection not involving the nasal septum or crossing the midline.
- B: bilateral alveolar maxilla and hard palate resected. Includes a small resection that crosses the midline of the alveolar bone including the nasal septum.
- C: removal of the entire alveolar maxilla and hard palate.

Maxillary defect reconstruction

Brown class 1 defects can be treated with local flaps, or with an obturator if there is an oro-antral or oronasal communication. Similarly, class 2a defects can be obturated, or reconstructed with local and pedicle flaps, or a combination of both. As the horizontal extent increases, such as in classes 2b and 2c, prosthetic rehabilitation with an obturator becomes more difficult and implant support may become necessary to improve stability. Consequently, a composite flap may be used to assist with soft tissue closure and provide bone for implant placement. Class 3 defects, involving midline and cross-midline structures, are usually not treated with obturators, because the weight and size of a device presents challenges in achieving a functional and stable prosthesis. For Classes 3b and 3c defects, a composite vascularized flap capable of addressing both maxillary and orbital defects is the recommended treatment. Class 4 defects

Fig. 50.2 Okay class Ib: defect resulting from excision of a pleomorphic adenoma.

Table 50.2 Summary of recommended treatment course for different maxillary defect classifications. (FF = vascular free flap; CFF = vascular composite free flap; OA = oro-antral fistula).

Classification of maxillary defects	Horizontal extent →	1 Palatal defect that does not involve the tooth-bearing alveolus	A Unilateral maxilla and palatal defect less than or equal to half of palate and alveolus, not involving the nasal septum	B Defect that crosses the midline, includes the nasal septum	C Defect involves the entire maxilla and alveolar bone
Vertical Extent ↓					
1 Removal of alveolar bone does not involve the nasal cavity or the maxillary sinus		Obturator, local or pedicle flap reconstruction required for palatal defect with nasal or antral involvement FF for larger defect			
2 Maxillectomy involving the nasal cavity and the maxillary sinus			Obturator Local or pedicle flap CFF	Obturator with implant support CFF	Large CFF required to close OA fistula, obturate orbit, and possibly close a cranial communication Prosthetic rehabilitation requires implant support
3 Maxillectomy involving the maxillary sinus, the nasal cavity, the orbital floor, with or without involvement of the anterior skull base			Obturator use possible but difficult with increased defect size and presence of trismus CFF	CFF Prosthetic rehabilitation requires implant support	Large CFF required to close OA fistula, obturate orbit, and possibly close a cranial communication Prosthetic rehabilitation requires implant support
4 Maxillectomy involving the maxillary sinus, the nasal cavity, exenteration of the globe with or without involvement of the anterior skull base			Large CFF required to close OA fistula, obturate orbit, and possibly close a cranial communication Prosthetic rehabilitation requires implant support	CFF Prosthetic rehabilitation requires implant support	Large CFF required to close OA fistula, obturate orbit, and possibly close a cranial communication Prosthetic rehabilitation requires implant support

are almost never amenable to obturator rehabilitation without free flap reconstruction, as they involve the entire orbit and sometimes the cranial base. A composite free tissue transfer that provides not only bone, but also a generous amount of soft tissue for closure of fistulas, obturation of the orbit, and sealing of cranial communications is needed.

Prosthetic obturation of maxillary defects

Staging of obturator fabrication

The postmaxillectomy defect undergoes significant changes as the tissues heal and remodel. Multiple

devices and modifications are required to adjust the rigid margins of the obturator to conform to the changing contours of the defect. The surgical obturator is the initial prosthesis used at surgery (Fig. 50.5a). This prosthesis addresses multiple factors to help the patient in the immediate postoperative period. The device restores palatal contours aiding speech and deglutition, provides support for surgical packing used to retain the skin or skin-substitute graft in place, and reduces wound contamination from the oral cavity. It can be wired to the remaining teeth or screwed to adjacent bone and is usually removed within 10–14 days to be replaced with an interim obturator. Generally, the surgical obturator is fabricated from acrylic, similar to a denture base plate, and does not contain teeth unless the esthetic zone is involved.

The interim obturator is inserted immediately after the surgical obturator is removed (Fig. 50.5b). This second prosthesis is used until healing is completed

and addresses both functional and esthetic needs. An acrylic base plate with teeth, clasps, and soft tissue liner is used to cover the surgical defect. Through close adaptation between the obturator and defect surfaces, retention is improved and fluid leakage into the nasal cavity is reduced, while optimizing speech and swallowing. The lining material is changed frequently to compensate for contour changes as the soft tissue margins contract and the bone margins remodel.

The definitive obturator is the final prosthesis, which is fabricated after tumor eradication has been confirmed and treatment and healing are complete, usually 6–12 months after ablative surgery (Fig. 50.6). Problems with comfort, function, retention, stability, and esthetics associated with the interim prosthesis can be addressed during design of the definitive obturator. Implant support to improve retention and stability is an option if bone is available in the appropriate sites.⁴

Fig. 50.5 (a) Immediate obturation of defect with surgical obturator. (b) Temporary obturation with an interim obturator.

Fig. 50.6 Definitive obturator

Facilitating obturator retention and stability

Removable obturators rely entirely on their physical characteristics for retention and stability. When reconstruction follows surgical ablation of pathology, the outcome for prosthetic rehabilitation can be improved significantly by recognizing, preserving, or enhancing those defect margins affecting retention. Mucosal coverage of the bony margins of the defect can be accomplished by placing the incision at least 0.5 cm beyond the planned osteotomy, thereby retaining a cuff of soft tissue that can be folded over the sectioned bone. Ulceration through this marginal tissue can be prevented by smoothing the bony edges before closure. Medial retention of the prosthesis is provided by engaging undercuts along the remaining maxillary bone, palatal shelf, or nasal floor. If the inferior turbinate encroaches into the defect, it should be removed since the associated undercut will most likely interfere with the paths of insertion and withdrawal. Lateral retention is provided by creating a mucosal scar band in the cheek along the margin between the cheek incision and a lining split-thickness skin graft (STSG). When possible, positioning this scar band high in the defect is preferable to placing it below the level of the medial undercut. Retention can also be aided by the addition of clasps around remaining teeth. The cuspids provide valuable anterior retention points, hence their inclusion in the Okay classification as a stratification measure. In order to preserve the periodontal health of remaining teeth, all efforts should be made to leave adequate bone support around the tooth adjacent to the planned osteotomy. This objective may require extraction of a tooth and placing the osteotomy through the dental socket.

Regardless of the attachment system used (marginal undercuts, tooth clasps, implants), reducing detrimental loading or displacement forces by enhancing obturator stability can prevent premature failure of the retention devices. Vertical stabilization and resistance to masticatory forces can be achieved

through preservation of the premaxilla when possible, and the use of overdentures with palatal coverage.⁵ Full extension of the obturator into all the recesses of the defect also provides load support and improved retention. Instability of an obturator is not only the result of masticatory loads. Displacement forces can also be created by speech and swallowing. When resection of more than one half of the soft palate is indicated, removing the entire velum should be considered, because this will augment retention, improve speech, and reduce fluid leakage. Large obturators that extend beyond the area of the maxillary tuberosity may be displaced during mandibular excursions by interference from the coronoid processes. A coronoidectomy is a simple remedy to this potential problem and may also prevent the development of trismus from postradiation fibrosis of the temporalis insertion.

Soft tissue coverage of defects

Using a split-thickness skin graft (STSG) enhances the retention and the stability of the prosthesis. A skin graft is more resistant to abrasion than respiratory mucosa and more suitable for prosthesis bearing. As the graft heals, it undergoes contraction, creating an undercut that can be engaged to improve the retention and stability of a prosthesis.⁶ Replacement of the respiratory mucosa with skin also improves hygiene by reducing secretions produced by glands normally present in respiratory tissue. STSGs are laid into defects with the dermal surface against the bone and secured in place for 2–3 weeks with compressive dressings composed of surgical packing or molded impression material (Fig. 50.7a). The packing is retained with a splint or bolster sutures placed along the margins and tied over the dressing. A successful skin graft will provide epithelial cover for all margins and surfaces of the resection (Fig. 50.7b, c).

Alternatives to autogenous skin include commercially available allogeneic, acellular dermal matrices. These have been used in a similar manner to STSG and offer several advantages, including reduced scarring and contraction and lack of donor site morbidity.⁷ However, the lack of contraction of allografts may also reduce the retention of the obturator. Additionally, the non-keratinized surface of dermal allografts is less resistant to friction created by movement of a prosthesis. The authors have observed an interesting fibroproliferative response in their use of allogeneic dermal grafts placed in maxillary defects. Over a period of several months, the grafts appear to stimulate the development of a significant amount of fibrous tissue that can bridge the entire defect (Fig. 50.8). The surface of the tissue is covered with epithelium, presumably regenerated from adjacent mucosal margins or from epithelial squames present in saliva. Obturation of a defect from an inlayed graft offers the advantage of closure of oronasal or oro-antral communications without the morbidity associ-

Fig. 50.7 (a) Split-thickness skin graft laid into maxillary defect. (b) Skin graft 2 weeks postoperatively. (c) Skin grafted maxillary defect with undercuts for prosthesis retention.

ated with other methods of soft tissue reconstruction, such as a rotational flap or free tissue transfer. However, prosthetic challenges are created whenever a maxillary defect is filled with soft tissue, whether from flaps or a local regenerative response; these will be discussed later in the chapter.

Implant support

Additional measures to improve the retention of an obturator include the use of dental implants. Advances in both implant and abutment technology have significantly improved outcomes. Shorter and wider implants can be accommodated within non-traditional sites in the remaining midface skeleton and have been shown to provide stability similar to longer implants through modifications to the implant surfaces (Fig. 50.9). The increase in survival rate of these shorter implants (8 mm or less) is the result of changes in surface geometry that increase surface area and porosity.⁸ Simultaneous advances in prosthetic implant attachments have also allowed less than ideally placed implants to be used as support for removable prosthetic devices. Locator attachments allow up to 40 degrees of divergence from the path of withdrawal along the implant axis. Custom abutments and cast bars with attachments can also be

Fig. 50.8 Fibroproliferative response in hemimaxillectomy defect following application of allogeneic acellular dermal graft. Proliferation of fibrous tissue has nearly filled the defect.

used to improve obturator retention. For those patients with defects amenable to placement of implants, prosthetic restoration is significantly improved from both esthetic and functional perspectives.

Adherence to sound prosthodontic principles and appreciation of an individual patient's entire condition, can lead to more successful outcome. In patients with malignant disease, the effect of adjunctive therapy, such as chemo-radiation-induced xerostomia,

Fig. 50.9 (a) Left maxillary defect reconstructed with vascularized fibula graft. (b) Short implants used to support an overdenture. (Courtesy of George Suchko, DDS.)

mucositis, or trismus, must be taken into consideration. Difficulty in cleaning and the potential for caries mitigate against fixed restorations such as crowns and bridges. While the most predictable restoration is an implant-supported overdenture, mucosal inflammation or xerostomia may preclude its use, and trismus may affect a patient's ability to insert the prosthesis. However, when used, the palatal coverage provided by overdentures reduces detrimental forces on implants that can lead to failure.⁵

The zygoma implant

This implant was originally developed for use in a severely atrophic maxilla to provide posterior retention without additional bone graft augmentation. For this application, the zygoma (or zygomatic) implant has proven reliable even when loaded immediately.⁹ Additional data to support use of this system were provided by Kahnberg *et al.*, who identified a high survival rate and patient acceptability of restorations over a 3-year period.¹⁰

Stability of the zygoma implant system relies on three points of fixation. Bilateral posterior support is achieved with implants placed through the zygomas and anterior support is provided by two endosteal implants placed in the anterior maxilla. This tripod configuration promotes cross-arch stability by linking the separate components together and providing retention to the principal displacement forces created by mastication.

Surgical placement involves the insertion of a long implant from the palate through the maxillary sinus to engage the bone at the junction of the temporal and frontal processes of the zygoma. Proper guidance of the drill and implant is facilitated by visualizing the path of insertion through a window created in the maxillary sinus wall. When possible, the head of the implant is placed within the thicker bone found at the junction of the palate and alveolar process of the maxilla.

When used for the reconstruction of maxillary defects where the palate, anterior maxilla, and inferior portions of the zygoma have been removed, three-point stabilization for a prosthesis is no longer possible and modifications to existing techniques are required. Anterior endosteal implant support is usu-

ally missing and the only bone available to engage the zygoma implants is provided by the superior portions of the zygoma(s) above the level of the zygomatico-maxillary osteotomy. This foundation is mechanically unstable for an attached prosthesis with poor resistance to lateralizing forces. There is also poor stability of the zygoma implants due to the long and unsupported lever arms. However, for patients with extensive defects unable to undergo grafting procedures to replace bone, the zygoma implant may be the only means for providing some form of retention for a maxillary obturator. One approach to the use of zygoma implants in patients following total maxillectomy, proposed by Schmidt, uses two implants placed at different angulations through the remaining zygoma bone (Fig. 50.10). These implants are allowed to integrate for 4–6 months before loading (Fig. 50.11). Coordinated planning with a prosthodontist results in a device that incorporates cross-arch stabilization by connecting all implants with a bar and clips (Fig. 50.12). Even with the adoption of these special measures, the zygoma implants experienced a 25% failure rate and anterior endosseous implants incorporated into the design failed 30% of the time. All failures occurred before loading, which suggests that non-mechanical factors were responsible for implant loss. Radiation therapy has been implicated as the principal cause of failure in these cases. When double implants are used on each side, prosthetic retention may still be possible following loss of a single implant.

Implants placed in irradiated bone

Radiation to bone causes a decrease in perfusion and a reduction in osteoblastic and osteoclastic activity.¹¹ As a result, an increase in implant failure and incidence of osteoradionecrosis is expected. Wagner cites a 3.4% incidence of osteoradionecrosis and close to 20% implant failure rate, after a 10-year follow-up of 60 patients who were radiated for oral cancer with over 60Gy.¹² Parel reports a similar experience describing a survival rate of 61.1% for craniofacial implants placed in irradiated bone. Other than words of caution and the usual rhetoric of “good patient selection”, consensus on methods to improve outcome in this particular patient population has not been reached. Although hyperbaric oxygen (HBO) therapy to improve implant success remains controversial, its beneficial effects on the tissue bed have been experimentally and clinically demonstrated.^{13,14} Most of the existing literature addresses implants placed after radiotherapy. It remains unclear if placing implants prior to the start of radiation improves the survival of implants.

Soft palate reconstruction

The decision to restore a soft palate defect with either a prosthetic device or surgical flap depends on size of the defect, number of teeth remaining to help support a prosthesis, and if there is a functional soft palate. Lesions of the soft palate and velopharyngeal complex are challenging defects for prosthetic rehabilitation, but tend to exhibit a better result than reconstructions of hard palate defects. Velopharyngeal closure can be achieved with an obturator and modifications can be performed as the dimensions of the defect change with healing. Soft tissue reconstruction with local or regional flaps is possible, but its effectiveness is governed by the site of the defect and the arc of rotation of the flap. If a flap is placed superiorly, it will hamper pharyngeal closure; if it is placed too inferiorly, it will interfere with both pharyngeal closure and seating of an obturator. Consequently, soft palate defects are better addressed with a prosthetic device (Fig. 50.13).

Local and regional flaps for maxillary reconstruction**Temporalis and temporoparietal-galea flaps**

The temporalis muscle flap was originally described by Golovine in 1898 for the obliteration of orbital defects following exenteration of the globe. Since then, it has been used to reconstruct different types of oral defects as an axial pattern rotational flap. Variations in technique have produced additional flaps composed of muscle and bone (temporalis-

Fig. 50.13 Obturator with soft palate extension to assist with velopharyngeal closure following excision for squamous cell carcinoma.

coronoid flap) or flaps composed entirely of the temporalis fascia with or without an attached cutaneous island (temporal fascial/fasciocutaneous flaps).

Temporalis muscle flap

The temporalis muscle arises from two regions on the skull, the temporal and infratemporal fossae, and inserts into the coronoid process. When used for oral reconstruction, this fan-shaped flap is based inferiorly on its coronoid insertion and rotated anteriorly and inferiorly into the defect site. Relative to its vascular supply, the temporalis muscle flap can be divided into three regions. The anterior portion is supplied by the anterior deep temporal artery while the middle portion is supplied by a pair of posterior deep temporal arteries. Both deep temporal branches arise from the internal maxillary artery and enter the muscle from the inferior aspect and on the deep surface. The posterior portion of the flap is supplied by the middle temporal artery, a branch of the superficial temporal artery, which also enters the muscle on its deep surface. Venous drainage and innervation from the anterior and posterior deep temporal nerves follow the same orientation as the arterial supply. Depending on the size of the defect, the temporalis muscle may be divided longitudinally into an anterior one-third flap or a posterior two-thirds flap. If necessary, the location and direction of the anterior and posterior deep temporal vessels can be confirmed with a Doppler probe following elevation of the muscle from its temporal origins.

Access to the muscle is gained with a hemicoronal or bicoronal scalp incision extending superiorly from the preauricular crease (Fig. 50.14). The coronal portion of the incision may be curved posteriorly to avoid the superficial temporal vessels. This incision is deepened through the temporoparietal fascia until the deep temporal fascia is identified. Once this structure is reached, blunt dissection in the loose areolar plane superficial to the fascia is performed in an anterior direction to expose the fascia. The preauricular inci-

Fig. 50.14 Access to temporalis muscle through hemicoronal incision. (Courtesy of Brian Schmidt, DDS, MD, PhD.)

sion is then deepened to reach the base of the zygomatic arch and the periosteum covering the arch is divided at a distance no more than 8mm from the root of the arch to avoid temporal branches of the facial nerve that cross the arch within the superficial layer of the deep temporal fascia. After the scalp and preauricular incisions have been connected, the deep temporal fascia is incised and a plane superficial to the muscle and continuous with the sub-periosteum over the arch is developed superiorly and anteriorly exposing the temporalis muscle. The fan-shaped muscle is elevated from the temporal fossa after division of the superior attachments to the cranium. From its base on the coronoid process, the muscle flap is rotated laterally over the zygomatic arch and inferiorly through the infratemporal fossa into the oral cavity. For high maxillectomies, direct access to the

mouth is achieved through the defect. With low maxillectomies, a vestibular incision in the molar area creates a communication with the infratemporal fossa for passage of the flap, taking care to avoid Stensen's duct. The zygomatic arch may be removed if it hinders rotation of the flap. The muscle flap is then sewn to the mucosal margins of the defect and, if necessary, stay sutures threaded through the bone may be used to prevent muscle retraction (Fig. 50.15). The muscle surface may be skin grafted or left bare to epithelialize secondarily (Fig. 50.16).

If a smaller amount of tissue is needed to obturate the maxillary defect, the temporalis muscle may be divided vertically at the junction of the anterior and middle one-thirds, behind the course of the anterior deep temporal neurovascular bundle. After the anterior portion of the muscle is delivered, the posterior two-thirds can be rotated anteriorly to fill the temporal defect to reduce postoperative temporal hollowing. Temporal hollowing may also be corrected with implants fabricated from alloplastic materials such as polymethylmethacrylate molded to fill the defect or prefabricated implants composed of porous polyethylene custom-prepared from stereolithographic models.

Variations of the temporalis muscle flap include a superiorly based flap, incorporating the coronoid process osteotomized at the level of the sigmoid notch, and inferiorly based flaps attached to a piece of the outer table of the temporal bone to provide both muscle and bone to reconstruct maxillary defects that include the orbital walls. The temporalis muscle flap may also be wrapped around titanium plates and mesh used for orbital and midface reconstruction.

Temporoparietal-galea flap

This is an axial pattern flap and may be used in a similar fashion as the temporalis muscle flap for maxillary reconstruction. Instead of muscle, it is composed of

Fig. 50.15 (a–c) Class 2a maxillary defect reconstructed with temporalis muscle flap. Flap is delivered intraorally through vestibule and sewn into defect. (Courtesy of Brian Schmidt, DDS, MD, PhD.)

Fig. 50.16 Temporalis muscle flap 2 weeks after insertion. Note secondary epithelialization.

the temporoparietal fascia, part of the subcutaneous musculoaponeurotic system (SMAS). It is a thinner flap and is used when a less bulky soft tissue reconstruction is desirable, such as for coverage of metal plates or bone. The vascular supply of this flap is derived from the posterior branch of the superficial temporal artery, which forms when the artery divides into anterior and posterior branches 2–4 cm above the arch. The vessels travel in the temporoparietal fascial layer and must be preserved during the superficial and deep dissections to expose the flap. Using a hemicoronal incision, a superficial dissection is made in a plane just below the subcutaneous layer of the skin. Hair follicles superficial to the level of dissection confirm that the correct plane has been achieved. The attachment between the underlying temporoparietal galea and the overlying skin can be tenacious and this dissection should be carried out carefully. After elevation of the skin, the course of the superficial temporal artery and branches should be identified visually and with the assistance of a Doppler probe (Fig. 50.17). The flap is rectangular in shape and based inferiorly at the level of the zygomatic arch. To create the posterior margin of the flap, a vertical incision is made behind the posterior branch of the superficial tempo-

Fig. 50.17 Temporoparietal–galea flap: elevation of the skin at the subcutaneous level exposes the galea. Superficial temporal vessels and branches are visualized through the galea.

Fig. 50.18 Rectangular temporoparietal–galea flap elevated.

ral artery and vein through the temporoparietal fascia to the underlying muscle. The length and width of the flap is determined by the size and location of the defect and this can be gauged with the assistance of a suture or umbilical tape rotated into the defect from a pivot point placed at the base of the flap. Before creating the anterior vertical incision of the flap, the anterior branch of the superficial temporal artery must first be ligated. Between the fascia and muscle is a layer of loose areolar tissue, which provides an easy plane for completion of the deep dissection (Fig. 50.18). The flap is rotated into the oral cavity in a similar manner as the temporalis muscle flap.

Buccal fat pad flap

Ideally suited for small retromolar and posterior maxillary defects, this axial pattern flap enjoys a robust blood supply with contributions from the buccal and deep temporal branches of the maxillary artery, the transverse facial branch of the superficial temporal artery, and buccinator branches from the facial artery. Within the fat pad, a network of small arterioles and venules is present and care must be taken to avoid disruption of these vessels through overzealous manipulation. The fat pad is multilobular with each lobe enclosed within a thin capsule and attached to adjacent structures by supporting ligaments. Variations in position of the fat pad occur throughout life accounting for the full facial contours present in infants and the hollowed appearance of the cheeks in the elderly. However, the volume of the fat pad remains fairly constant and has been estimated to be approximately 10 ml. The fat pad is organized into anterior, intermediate, and posterior lobes, with four processes (buccal, temporal, pterygoid, and pterygopalatine) extending from the posterior lobe. The different lobes lie between the buccinator medially, masseter laterally, the ascending ramus of the mandible posteriorly, and the zygoma superiorly.¹⁵ The central corpus composed of the anterior and intermediate lobes along with the buccal process of the posterior lobe represent the major components of the buccal fat pad flap (BFPF) used for reconstruction. The buccal branches of the facial nerve and the parotid duct are lateral to the fat pad and are usually not encountered during flap development.

If access to the fat pad has not already been created by the ablative procedure, an incision in the vestibular sulcus distal to the maxillary tuberosity through the periosteum will expose the buccal fat pad.¹⁶ After widening the access to prevent constriction of the BFPF pedicle, the flap is placed under tension at its leading edge while blunt dissection mobilizes the flap by dividing the supporting ligaments. Between 7 and 9 cm of length may be achieved and the flap is sewn to the defect margins either with sutures to a soft tissue margin or tied to holes drilled through the bony margins. The BFPF is a highly versatile surgical tool in maxillary reconstruction and can be used to

close class I and IIa maxillectomy defects, oro-antral communications, and lateral wall and palatal voids. However, defects larger than 4 cm in diameter, or in irradiated fields, may not be suitable for reconstruction with a BFPF.¹⁷ Although the buccal fat pad has been used as a vascularized bed to cover a bone graft during maxillary reconstruction,¹⁸ it is not sufficiently reliable for this purpose.

The BFPF epithelializes rapidly, rendering additional coverage with STSGs unnecessary. Initially, the flap surface is covered with granulation tissue and this undergoes a hyperkeratotic response before the surface fat cells are transformed into a thickened stratified squamous epithelium over a period of 5 weeks (Fig. 50.19).¹⁹ The BFPF technique is associated with low morbidity and produces minimal contour changes and facial asymmetry. The only problem is obliteration of the maxillary vestibule in the region where the flap traverses from the cheek to the maxilla, and this may compromise stability of a prosthesis (Fig. 50.20).

Preserving space after bone removal

Immediate reconstruction following tumor removal or immediately after an avulsive injury is infrequently performed, despite the benefits of ready access to the defect, lack of soft tissue contraction from scarring, and early return to function. Large, avulsive injuries following trauma typically involve the loss of hard and soft tissue, with the potential for additional tissue necrosis as the delayed effects of vascular damage become apparent. Consequently, immediate reconstruction is not undertaken in most trauma patients. For defects resulting from tumor ablation, concerns over disease eradication mitigate against immediate reconstruction. However, defects created during the treatment of localized, benign disease may be addressed at the time of removal and this approach provides the optimal functional and esthetic result (Fig. 50.21).

One of the problems associated with delayed reconstruction is scarring of the soft tissue envelope

surrounding the skeletal defect. This can limit the size of the graft that can be used, especially with regards to skeletal height. To preserve the dimensions of the missing skeletal bone, a methylmethacrylate (MMA) space maintainer can be used (Fig. 50.22a, b). Dehiscence of the overlying soft tissue with exposure of the device remains an issue, although there are several reports supporting its use.²⁰ In the authors' experience, problems with wound healing can be

reduced by achieving a tension-free closure around the spacer, rigidly fixating the implant in place, and limiting the interval between device implantation and secondary reconstruction of the defect. If there are concerns over bacterial wound contamination, a broad-spectrum antibiotic (a non-heat-labile antibiotic such as tobramycin or vancomycin) can be incorporated with the MMA device.²¹ Another use of the spacer is as a template to fashion a bone graft for

Fig. 50.23 (a) Radial forearm free flap harvest; paddle outline. (b) Radial forearm flap; vascular pedicle.

a more precise fit (Fig. 50.22c, d). MMA for these purposes is available as bone cement in sterile packaging, with and without antibiotics and in different viscosities. When used, attention should be paid at the time of secondary bone graft placement to remove any granulation tissue and the fibrous capsule which forms around the spacer to allow the early establishment of a vascular supply to the bone graft.

Free tissue transfer in maxillary reconstruction; soft tissue obturation

Where the maxillectomy defect involves the orbital adnexae or more than half of the maxillary alveolus, obturation with a prosthesis will rarely give a satisfactory outcome. In such cases surgical solutions provide superior results and patient satisfaction.²² Free tissue transfer using microsurgical anastomotic techniques has revolutionized reconstructive surgery over the last 30 years. The ability to import tissue to the head and neck from donor sites elsewhere in the body provides sources of reconstructive tissue which can be tailored to the specific requirements of the defect for an individual patient. These include both soft tissue only flaps (fasciocutaneous, e.g. radial forearm and anterolateral thigh, and musculofasciocutaneous, e.g. latissimus dorsi and rectus abdominus) and also composite soft and hard tissue flaps (osteocutaneous, e.g. fibula flap, and osteomyocutaneous, e.g. vascularized iliac crest with internal oblique with or without skin). There are challenges in reconstructing the midface in order to provide adequate restoration of form and function. A further major consideration is the distance of the recipient bed from donor vessels in the neck and a pedicle of adequate length is required for successful reconstruction.

Radial forearm free flap

First described in China by Guofan *et al.* in 1981,²³ the use of the radial forearm fasciocutaneous free flap

Fig. 50.24 Type I maxillectomy defect reconstructed with radial forearm flap contoured to recreate the buccal sulcus. Patient is able to wear a standard maxillary denture.

was described in 1982 by Muhlbauer for use in the oral cavity. It was further popularized as a reconstructive tool for the oral cavity by Soutar.²⁴ This flap is now regarded as a reconstructive workhorse in the head and neck generally, providing a reliable paddle of pliable fascia and skin to restore both function and cosmesis.

The flap is raised on the radial artery and venae comitantes vessels. The superficial venous system (cephalic vein) may also be raised and traced proximally either as a separate venous pedicle or to the venae perforantes which unite the superficial and deep venous systems (Fig. 50.23).

In the context of the limited maxillectomy defect (class 1), and especially in the edentulous patient, closure of the defect with this flap produces predictable and satisfactory outcomes. Here the flap is tailored to the size of the defect and, once inset, replaces the lost tissue as well as the upper buccal sulcus, facilitating retention of a complete denture prosthesis (Fig. 50.24). The pedicle is passed along a tunnel fashioned within the buccal tissues and the artery and vein(s) anastomosed to suitable vessels within the neck. Advantages of this technique include reliability of the flap, a long pedicle, and good-sized vessels, which facilitate anastomosis to vascular sources in the neck.

Where the defect is of greater dimensions (Brown class 2 and greater) the reconstructive aims will be tailored according to the overall oral rehabilitation plan for the patient. Ideally, adequate bone to support osseointegrated implants, together with appropriate soft tissue coverage are required to restore form and function. Previously, use of larger soft tissue free flaps such as rectus abdominus^{25–27} and latissimus dorsi^{26,28–34} myocutaneous flaps was described. While these provide adequate obturation of the maxillary defect, such bulky flaps often result in a ptotic soft tissue mass which makes prosthetic rehabilitation extremely challenging, if at all possible. Furthermore, flap ptosis can impair function, such as speech and swallowing. Facial form restoration is also suboptimal.³⁵

When skeletal and alveolar augmentation is needed to support implant placement, the free tissue transfer technique must include bone. While none of the available reconstructive options can accurately replace all the lost tissue, each of the options provides varying quality of tissue with which to obturate the defect, restore form, and provide a basis for osseointegrated implants. The principle flaps used in this regard include the radial forearm osteofasciocutaneous flap, the fibula osteofasciocutaneous flap, the scapula osteocutaneous flap, and the vascularized iliac crest with internal oblique muscle graft.

Radial forearm osteofasciocutaneous flap

The radial forearm flap, incorporating a segment of the radius, was initially described by Soutar in mandibular reconstruction³⁶ and more recently in the maxilla.^{37,38} This flap has the advantage of two-team harvest and a long and reliable pedicle. The flap is also a variant of the soft tissue only radial forearm free flap and the anatomy and surgical procedure are therefore very familiar to operators in the field of head and neck reconstruction. Bone of the distal radius can be harvested to a maximum of 40% of the diameter and up to 16 cm of the length of the radius. This provides somewhat limited bone stock and the flap is therefore best suited to smaller defects of the premaxillary region, maxillary alveolus and orbital rim^{39–41} rather than larger class 2 and greater maxillectomy defects. This flap does not provide adequate bone to support implants.

The vascular supply to the radius is developed by preserving periosteal perforators from the radial vascular pedicle, composed of the flexor pollicis longus and pronator quadratus muscles. Access to the bone is gained by incising through the muscles on the ulnar aspect and preserving the radial attachments. The harvested bone segment is freed by dividing the brachioradialis muscle laterally. This is illustrated in Fig. 50.25.

While this technique provides a reliable reconstructive flap which can be raised simultaneously by

a second surgical team, the limited bone restricts its utility to smaller defects.^{39–41} Donor site morbidity includes fracture of the remaining radius. This is reported in a small proportion of cases and can be minimized with appropriate fixation techniques. Fig. 50.26 is a radiograph demonstrating plate fixation of the radius after osteocutaneous forearm flap harvest.^{42,43}

Fibula osteocutaneous flap

This flap was originally developed to reconstruct ulna and tibial defects⁴⁴ and was later adapted for use in mandibular reconstruction.⁴⁵ After gaining popularity as a reliable method for mandibular reconstruction,⁴⁶ it was later applied to the maxillectomy defect where it has become a workhorse.^{37,47–49} The fibula flap is based on the peroneal artery and vein and provides the greatest length of available bone of any composite free flap (Fig. 50.27). From an anterior incision, perforator vessels from the peroneal artery, which supply the fasciocutaneous tissue, are identified, prior to outlining a skin paddle. The paddle is centered on these vessels, thereby increasing the survival of the skin portion of the flap (Fig. 50.28).

The bony component of the flap is triangular in cross-section and narrow and comprised mainly of compact cortical bone. The bone can be folded on itself in a “double-barrel” arrangement to increase the height of the graft, but this is more of a concern with mandibular reconstructions.⁵⁰ Pedicle length is limited by the site of bifurcation of the tibioperoneal trunk into the peroneal and posterior tibial arteries. The usual pedicle length is around 6–7 cm, but this can be increased by subperiosteal dissection of the fibula more proximally to produce a pedicle of 12 cm (Fig. 50.29).⁵¹ While revision of the graft, primarily to reduce the bulk of the soft tissue, is usually required prior to prosthetic rehabilitation of the patient, the fibula flap can achieve an excellent reconstruction of a maxillary defect (Fig. 50.30). It is capable of completely sealing the mouth from the nasal and antral cavities and provides sufficient bone to support implant placement.

Scapular angle osteomyogenous flap

A series of cases using this reconstruction method for the maxillectomy defect was described recently by Gilbert and coworkers in Toronto.³⁵ The scapula free flap has been used extensively in mandibular reconstruction since the first recognition of this donor site in 1978 by Saijo.⁵² Described specifically for reconstruction of the maxilla and mandible later by Swartz, this flap is a popular choice for head and neck reconstruction, offering versatility of orientation of skin paddles and bony paddles as well as the inclusion of muscle paddles where required.^{32,34,53–57}

The scapular angle osteomyogenous flap is particularly suited in the elderly patient population,

Fig. 50.25 (a) Skin markings for radial forearm osteocutaneous flap. (b) Bone marked for osteotomies prior to radial bone harvest. (c) Osteotomies created with reciprocating saw. (d) Radial forearm osteocutaneous flap prior to pedicle division. (e) Flap prior to pedicle division. Note preservation of flexor pollicis longus and pronator quadratus through which periosteal perforators run.

because of the increased incidence of peripheral vascular disease. Additionally, these patients may have difficulty ambulating after fibula flap harvest.³⁵ It is also a reliable flap with low failure rates and minimal donor site morbidity.³⁵ Advantages of this flap for use in midface reconstruction include a generous pedicle length up to 20 cm and the vessels are sufficiently large to facilitate microvascular anastomosis (Fig. 50.31). Scapular bone is similar in structure to the native maxilla, being thin medially and thicker toward the lateral border. Consequently, the bony component of this flap is harvested from the lateral margin of the scapula. Average thickness at this site is approximately 28 ± 3 mm,⁵⁸ which is adequate for implant placement, but of inferior quality when compared with the type I bone normally associated with the fibula or iliac crest.^{59,60}

The scapular bone is easy to contour using a “greenstick” method where one cortex is sectioned and the other curved by manipulation. The flap can be oriented vertically to restore the nasomaxillary

Fig. 50.26 Postoperative radiograph of donor arm after osteocutaneous radial forearm flap harvest and fixation.

Fig. 50.27 (a, b) Fibula flap harvest skin markings. Note the 8 cm length of bone maintained proximally and distally in order to ensure stability of the knee and ankle joints respectively. The perforator zone is marked, where perforator vessels run around posterior to the fibula and then in the posterior intermuscular septum to supply the skin paddle. Making an anterior incision to allow precise identification of these perforators increases reliability of the skin paddle.

Fig. 50.28 (a, b) Development of a skin paddle. Perforator vessels from the peroneal artery passing through the posterior intermuscular septum into the fasciocutaneous paddle are demonstrated. The soft tissue component is centered on these vessels facilitating flap survival.

and zygomaticomaxillary buttresses or horizontally to replace the palatoalveolar complex in a similar fashion to that described by Brown with the vascularized iliac crest.⁶¹ In order to harvest a scapula flap, the patient must be turned to the lateral decubitus position (Fig. 50.32). A two-team approach is therefore not possible when using this technique, which adds to operative time. Clark *et al.* describe the use of a suction bean bag to achieve and maintain patient orientation during flap harvest.³⁵

Vascularized iliac crest with internal oblique muscle flap

This technique is unique in providing adequate bone to restore both facial and oral skeletal structures in both low- and high-level maxillectomy defects. Adequate bone stock is therefore available for the placement of dental implants.

Initial development of the flap, supplied by the deep circumflex iliac artery (DCIA), occurred in

Fig. 50.29 Fibula flap harvest prior to division of the pedicle. The fasciocutaneous paddle has been developed and osteotomy of the proximal end of the fibula demonstrates the triangular cross-section of bone obtained.

England and in Australia,^{62,63} before the technique was adopted for mandibular reconstruction by Urken and colleagues.^{64,65} This group reported a large series of cases with high success rates and low donor site morbidity.⁶⁶ In addition to excellent bone volume available from this site, the accompanying internal oblique muscle, supplied by the ascending branch of the DCIA, provides excellent soft tissue for bone coverage and defect obturation. This technique has now been adopted for use in midface reconstruction^{22,37,61} and a large series using this method has been reported by Brown and colleagues.³ Low-level maxillary defects can be reconstructed with the bone flap oriented horizontally; higher-level defects position the bone flap vertically.⁶¹ In this study 87% of patients who survived the primary disease progressed to full oral rehabilitation with dental implants. Donor site problems are minimal and flap complication rates reduced with increasing experience of the operators. The vascularized iliac crest is therefore the most suc-

Fig. 50.31 Scapular osteomyocutaneous flap.

cessful technique in the armamentarium of microvascular surgeons for the rehabilitation of midface defects after surgery for cancer or trauma.

This technique is illustrated in Figs 50.33–50.36 and the sequence of operative events is described. An expanding lesion in the left posterior alveolus was diagnosed as a chondrosarcoma of the left maxilla. Control of regional disease was established with a selective lymphadenectomy of levels 1–3 with preservation of the facial artery and vein at the lower border of the mandible for the graft anastomosis (Fig. 50.33a). Once this had been completed, resection of the left maxilla through a modified, extended Weber-Ferguson incision was performed (Fig. 50.33b, c). Simultaneous with the ablative procedure, a second surgical team is able to raise the vascularized iliac crest graft. The incision line and femoral vessels are marked. The contour of the ipsilateral iliac crest is similar to that of the corresponding maxilla and is therefore selected. The internal oblique muscle is

raised on the deep circumflex iliac vessels and this forms the pedicle for the underlying crestal bone harvest (Fig. 50.34).

Once the graft has been harvested, the bone is trimmed and shaped to match the maxillary defect and the flap inset and fixated in position with bone plates (Fig. 50.35a, b). The vascular pedicle is tunneled through the buccal tissues to reach the facial vessels in the left neck and access for the anastomosis facilitated by dividing the mandible temporarily with a parasymphiseal osteotomy. The integrity of the oral lining is restored by suturing the internal oblique muscle to the buccal mucosa laterally and nasal and palatal mucosa medially and this completes obturation of the maxillary defect (Fig. 50.35c). The final views demonstrate the excellent facial contour reproduced by the iliac crest vascularized flap (Fig. 50.36).

Conclusion

Maxillary defects pose significant reconstructive challenges. This chapter presents an account of the various techniques, both biological and alloplastic, that have become the principal methods for addressing these defects. The final choice is based on several factors, principally the etiology of the defect, a patient's ability to undergo major reconstructive surgery, and, finally, the expertise available to treat the case.

Chapter 51

Mandibular Reconstruction

M. Anthony Pogrel and Brian L. Schmidt

This chapter describes the reconstruction techniques available after marginal and segmental resection of the mandible. The non-vascularized bone grafting procedures available, including rib grafting, corticocancellous block grafting, and marrow grafting in a crib, are described. The techniques for obtaining bone grafts from the ribs, anterior iliac crest, posterior iliac crest, and tibia are described. The principles of microvascular free bone grafting to reconstruct the mandible are described. The advantages and disadvantages of staged reconstruction versus one or two procedures are described, covering the spectrum from primary bone grafting to provision of osseointegrated implant-retained prostheses. The effects of radiation therapy on mandibular reconstruction are also discussed.

Whenever a portion of the mandible is resected, consideration must be given to subsequent reconstruction. Although most patients do receive mandibular reconstruction following resection there is still a minority for whom no reconstruction may be the most practical alternative. These cases particularly include shorter lateral defects, not involving the symphysis and parasymphysis areas, in elderly or

medically compromised patients. The subsequent deformity in the absence of reconstruction is often acceptable under these circumstances. However, at present, the “gold standard” for reconstruction is autogenous bone.

Marginal resection

Marginal resection of the mandible may be indicated for the excision of a benign tumor, a superficial malignant tumor involving periosteum only, or for infection. In this case mandibular continuity is not disrupted. However, the mandible is at risk for subsequent fracture, particularly if radiation therapy has to be given.¹ For this reason, reconstruction is often performed. Bony reconstruction will also enable subsequent insertion of osseointegrated implants, if indicated, to complete prosthodontic reconstruction. In a young patient reconstruction may not be necessary since some spontaneous regeneration of bone may occur, particularly if the periosteum is retained.² However, the mandible may need to be reinforced with a reconstruction plate (usually around 2.4 mm in thickness with appropriate screws) to minimize the risk of fracture. Following marginal resection, reconstruction can be with corticocancellous blocks from the iliac crest (full thickness or partial thickness), which can be contoured so that they will mortise into place with minimal or no fixation (Fig. 51.1). For a lesion less than about 3 cm in size this can be carried out immediately from an intraoral approach; for defects greater than this, consideration should be given to carrying this out secondarily and possibly from an extraoral approach, to avoid the risk of graft failure due to infection secondary to salivary contamination. Subsequent soft tissue grafting is often necessary to supply attached mucosa for denture or implant insertion. This is often carried out by means of a split-thickness skin graft, and normally done as a secondary procedure following incorporation of the bone graft.

Fig. 51.1 A marginal resection of the mandible for a fibro-osseous lesion (a) reconstructed with an iliac crest bone graft morticed into place intraorally at the time of the primary resection (b) and secondarily skin grafted and implants inserted and an implant supported restoration placed (c, d).

Segmental resection

Segmental resection of the mandible with loss of mandibular continuity may be necessary for benign or malignant lesions, as well as for chronic infection.

Fig. 51.2 A fractured reconstruction plate used to span a segmental defect, which had not received a bone graft.

Temporary immediate reconstruction is often carried out by means of a reconstruction plate, but these are rarely satisfactory for long-term use. The usual history is for the plate to either exteriorize itself and become secondarily infected, or for screw loosening and mobility to occur. Depending on the forces placed on it, these problems will normally occur after some 18 months or 2 years. Plate fracture has also been reported (Fig. 51.2). In particular, reconstruction plates fail most frequently in the anterior mandible, but can survive in the long-term in the body and posterior parts of the mandible, particularly if there is adequate soft tissue coverage, which may have to be in the form of a soft tissue flap, such as a pectoralis major flap.³

Nevertheless, it is generally more appropriate to reconstruct the mandible with non-vascularized autogenous bone. Non-vascularized autogenous bone is normally used as a secondary procedure. Immediate segmental reconstruction with non-vascularized autogenous bone from an intraoral approach has been associated with a high failure rate, although it was recommended by Obwegeser amongst others.⁴⁻⁶ The reasons for failure are generally wound breakdown intraorally and contamination of the wound with saliva, or primary infection due to oral contamination. Reconstruction is therefore more normally carried out secondarily. The most appropriate time to carry this out would appear to be some 6–8 weeks following primary resection for the following reasons:^{7,8}

- this gives the intraoral wound time to heal and gain some tensile strength;
- the wound bed has time to self-decontaminate;
- scarring and fibrosis have not had an opportunity to develop.

Resection is often carried out from a combined intraoral and extraoral approach, and temporary reconstruction is carried out with a titanium reconstruction plate (usually a 2.4mm plate is adequate). Some 6–8 weeks later, definitive reconstruction is carried out from an extraoral approach using autogenous bone. Depending on the circumstances, this can be by the use of autogenous ribs (usually in a younger patient)

(Fig. 51.3), corticocancellous blocks from the iliac crest (full thickness or partial thickness) (Fig. 51.4), or cancellous bone marrow in a carrier tray.⁷ The tray can be of titanium mesh or an allogenic bone tray (Fig. 51.5), or in exceptional circumstances, it may be an autogenous bone tray, since it may be possible to carry out a segmental resection of the mandible for a benign lesion, excise the lesion from the mandible, and reinsert it as its own carrier tray.

Over the years, many attempts have been made to reconstruct the mandible using the actual autogenous mandible that was previously resected. In the case of a benign lesion, it may be possible to resect the mandible, remove the lesion, and reinsert the mandible. In most cases this does mean hollowing the mandible out to resemble a tray, perforating the tray, and

securing it with a reconstruction plate, and then completing the reconstruction with autogenous marrow within the tray. This does give the most esthetic reconstruction, since it is the patient's own mandible and therefore the contour is the most acceptable. Fig. 51.6 shows this technique used for a high-flow vascular malformation of the mandible. When this treatment is contemplated for aggressive lesions, or even malignant lesions, the resected mandible must be "sterilized" in some way to kill unwanted cells. In most cases the technique is as just described, in removing the lesion from the resected mandible, reducing the mandible to an autogenous tray and perforating it. Three different methods of sterilizing the mandible have been described. The first involves autoclaving the mandible;^{9,10} this will render the mandible non-vital, but most studies have shown that even with autogenous marrow grafting, excessive resorption normally occurs, and this technique is not widely practiced today. An alternative technique is to devitalize the mandible by means of cryotherapy,¹¹ and for this the mandibular tray is immersed in liquid nitrogen at -196°C for 10 minutes. The mandible is then allowed to thaw and is refrozen. Studies have shown that liquid nitrogen predictably causes cell death below -20°C and that the most satisfactory results are achieved with a rapid freeze and a slow thawing process. Although described in the literature, the technique does not appear to be widely practiced today. The third technique involves gamma irradiation of the mandible which will successfully devitalize the mandible,^{12,13} and does not appear to result in excessive resorption when it is reinserted and rigidly

Fig. 51.6 A vascular malformation of the left posterior mandible (a) which was resected, the lesion curetted out and the mandible recontoured as an autogenous tray which was reinserted, secured, and packed with autogenous marrow (b) into which implants were later inserted (c). (Courtesy of Janice S. Lee DDS, MD, MS.)

fixed and grafted. If a source of radiation is locally available, this technique can be carried out in one session while the patient is asleep and at the same time as the initial resection. The mandible can be cleaned, placed in a sterile autoclave bag and receive around 50Gy of radiation in less than 1 hour, in time for reinsertion into the patient. Otherwise, the procedure must be staged. Any of the above techniques may result in a more acceptable contour than using an autogenous graft from another part of the body.

Studies have shown that segmental resections of up to 6cm are associated with a high success rate when reconstructed by any of these techniques. Above 6cm the failure rate starts to increase and when the resected area exceeds 9cm the failure rate from a non-vascularized graft may be as high as 75%.⁷ Fig. 51.7 shows a successful 10cm non-vascularized graft even though it has undergone considerable resorption. Failure usually occurs because of failure of the bone graft to become vascularized and reincorporate, with subsequent infection and wound breakdown.

A number of factors have been identified which may improve or compromise bone healing and the incorporation of bone grafts on reconstruction. Platelet rich plasma (PRP), and possibly other platelet-derived and other growth factors, may enhance incorporation of bone grafts and also may enhance soft tissue healing.^{14,15} Early initial results were very promising, but some subsequent papers have cast doubts on the long-term success of these factors, which have decreased their popularity.^{16,17}

Bone morphogenic proteins (BMPs) have been identified but have only recently become commercially available. They have the ability to induce bone formation by recruiting osteoblastic stem cells to produce bone, thus possibly avoiding a bone graft. In the USA only BMP-2 is currently available,¹⁸ although in Europe BMP-7 (also known as osteoprotein or OP1) is also available.¹⁹ Although these show promise, it is

Fig. 51.7 (a) A 10cm non-vascularized full-thickness iliac crest bone graft to reconstruct a hemimandible including the condyle on removal from the hip. (b) Nine months later, after removal of the bone plate.

not known which of these factors is going to prove the most effective, and whether more than one factor is necessary to get the maximum enhancement of bone incorporation, and even whether there is a cascade process involved. At the current time, BMP-2 can only be utilized on an acellular bovine collagen sponge which is compressible and limits its usefulness to procedures such as sinus grafting for implants.¹⁸

When the bone graft has taken successfully, subsequent staged procedures include removal of the bone

plate. This may be necessary to allow subsequent vestibuloplasty and implant insertion. It may be necessary if the patient can feel the plate or screws beneath the tissue, if the plate appears to be in danger of exteriorizing itself, or if subsequent resorption of the bone graft is anticipated due to the effects of stress shielding. Stress shielding remains controversial in the maxillofacial regions. In the long bones, particularly the humerus, this has been shown to be a real issue in that when a rigid bone plate is removed after healing of a fracture of the humerus, it is not uncommon for refracture to occur since the bone plate has shielded the humerus from excessive forces, and therefore it has never fully remodeled and gained its pre-morbid strength. Although some studies have shown that stress shielding may be a factor in the healing of mandibular fractures, other studies have shown that it does not appear to be an issue.²⁰⁻²² Nevertheless, there are some patients who do seem to show excessive resorption following bone grafting, and it is felt that the presence of a rigid reconstruction plate may mean that the bone graft is not subjected to physiological forces, and therefore resorbs at an excessive rate. In these cases, removal of the bone plate may be advisable before the resorptive process becomes too pronounced. Timing of the removal of the plate is often critical, since one cannot remove it prior to the bone graft incorporating, but one wishes to remove it before excessive resorption has occurred. A time of between 4 and 9 months is normally quoted following the grafting procedure before removal of the bone plate. Occasionally bone plates also have to be removed for other reasons, including infection, screw loosening, plate fracture, and exteriorization of the plate or the patient being able to feel the plate through the soft tissues. Occasionally plates also cause discomfort with extremes of temperature. Following removal of the bone plate, it would be possible to carry out vestibuloplasty if necessary and to allow for subsequent osseointegrated implant insertion.

Non-vascularized bone grafting for mandibular reconstruction

Multiple sites have been advocated for obtaining bone that might be used for maxillofacial reconstruction. Some sites, such as the radius and ulna, are rarely used today. Cranial bone is used for post-traumatic reconstruction of the mid and upper face, but quantities are generally insufficient for mandibular reconstruction. The main sites used for non-vascularized mandibular reconstruction are ribs, the iliac bone, and the proximal tibia.

Ribs

Ribs can be used with a cartilage cap from the costochondral junction if they are required for temporo-

mandibular joint reconstruction,²³ or without cartilage for mandibular reconstruction, particularly in children.²⁴ In an adult, a considerable length of rib can be obtained (often up to 15 cm) accepting the curvature of the rib. Ribs are normally taken between the fifth and eighth ribs (avoiding the ribs with considerable attachment of the pectoralis major muscle and also avoiding the free floating ribs). Ribs can be taken from either side with equal ease.

This procedure is normally only carried out under intubated general anesthesia with the ability to administer positive pressure ventilation in the event of a pneumothorax. The surgical procedure involves identifying the rib or ribs to be taken and an incision is made directly over the rib. In females, the incision is normally placed beneath the breast or developing breast so that it will be hidden beneath the breast in the erect position. The incision is taken through the superficial musculature down to the periosteum and perichondrium. No major structures are encountered and only superficial bleeding vessels should be encountered. Once the periosteum of the rib has been identified, it is incised sharply down to the rib itself. If cartilage is to be taken, the incision should continue over the costochondral junction down to the cartilage.

At the anterior end of the incision through periosteum and perichondrium a T-junction should be made to limit the anterior extent of the perichondrial stripping, but to allow 4 or 5 mm of cartilage to be taken. A periosteal elevator is now used to strip the periosteum off the superior surface of the rib and cartilage. With great care, one then turns the corner and starts stripping periosteum from the superior and inferior surfaces of the rib. It must be remembered that the neurovascular bundle supplying the rib runs in a groove on the inner aspect of the inferior surface of the rib. It is crucial that the dissection be subperiosteal at all times. The dissection is then continued with care on the inferior surface of the rib. Although normal periosteal elevators can be used for this dissection, special instruments are available, such as the elevator (Fig. 51.8).

Once the subperiosteal dissection has been completed and the rib isolated, an instrument such as the appropriate Doyen retractor can be placed under the rib and the subperiosteal dissection confirmed and continued (Fig. 51.9). The rib is always sectioned at the anterior end first. If this is in cartilage, it can be carried out with a scalpel, but an instrument must be placed under the cartilage to prevent penetration of the pleura. If the anterior sectioning is to be in rib bone itself, then a guillotine or rib shears can be used. Once the anterior cut has been made, the rib can then be raised and, with ease, the subperiosteal dissection can continue as far posteriorly as required for the length of rib needed. Once the posterior limit has been defined, the posterior cut through the rib is normally made with a guillotine, which protects the underlying structures (Fig. 51.10). Once the rib has been taken, it is laid on one side and covered with moist gauze.

Fig. 51.8 (a) An Overholt periosteal stripper to raise periosteum around a rib. (b) Note the T-shaped incision through the periosteum.

Fig. 51.9 (a) Doyen retractor (b) placed under a rib to elevate periosteum, protecting the underlying pleura.

A test is now made for the presence of a pneumothorax, and since the procedure is carried out under intubated general anesthesia, this is most easily carried out by filling the chest wall cavity with warm saline and allowing the anesthesiologist to fully inflate the chest (a Valsalva maneuver). Any bubbling will indicate a pleural leak. If the leak is very small, it may be oversewn directly, but the sutures should

Fig. 51.10 (a) A guillotine rib (b) cutter used to cut the posterior end of the rib.

only be tightened down in conjunction with another Valsalva maneuver to drive all the air out of the pleural cavity. If the leak is a little larger, a drainage tube can be placed, and then a purse-string suture placed around it; the drainage tube is withdrawn as the purse-string suture is tightened on another Valsalva maneuver and this may give good closure of the hole (Fig. 51.11). If closure cannot be obtained, then an underwater sealed drain must be inserted, and this will normally go from the opening and emerge high in the chest in order to drain air. This drain will be placed to low-volume wall suction and left in place for 24–36 hours.

If more than one rib is required, then the adjacent rib can normally also be harvested in the same way through the same incision. If more than two ribs are required, then it is necessary to leave alternate ribs so that the patient does not develop a flail chest. Sometimes this requires a second chest wall incision, but sometimes it can be obtained through the one incision if it is correctly placed. Closure is carried out in layers and postoperatively an upright chest radiograph is obtained as soon as possible to check for the presence of a pneumothorax. With any pneumothorax occupying more than about 15% of the lung

Fig. 51.11 A pursestring suture round a drainage tube to close a small pneumothorax.

volume, an opinion should be obtained with regard to placement of an underwater sealed drain. At the completion of the surgery, a long-acting local anesthetic, either given as a single injection or via a subcutaneous infusion device, can make postoperative physical therapy and chest movement more acceptable to the patient.²⁵ Chest wall discomfort is to be expected on deep inspiration for some time after this procedure. Postoperative physical therapy with inspiratory spirometry is often indicated.

When the wound is closed, attention can now be turned to the harvested ribs. If it is required to include costochondral cartilage, this can now be shaped with a scalpel to leave a cap of about 2 mm of cartilage on the end of the rib (Fig. 51.12). This approximates well to a temporomandibular joint. If more cartilage is left, there is a risk of it separating from the rib on pressure, and also more risk of overgrowth occurring from the cartilage. The rib can be effectively straightened with a rib morcellizer, but care must be taken not to splinter the rib. Ribs from younger people will straighten more easily than ribs from older patients. When securing ribs in place with screws, they generally require a washer of some kind to prevent the screw from splintering the rib. In some cases it is preferable to use a bone plate and put the plates and screws through the plate, or even titanium mesh and place the screws through the mesh, so the pressure is spread more evenly.

Iliac crest

Anterior iliac crest

This donor site is the workhorse of the reconstructive oral and maxillofacial surgeon.²⁶ The landmark of the anterior iliac spine can normally be identified by palpation on all but the most obese patients and the outline of the crest of the ilium can also be mapped out on the skin. The initial incision should not be placed right over the crest since this can be uncomfortable postoperatively with some clothing. It is also advisable to hide the incision below the crest of the ridge in

Fig. 51.12 Two ribs with cartilage caps to reconstruct the temporomandibular joints.

Fig. 51.13 Site of the incision to approach the anterior iliac crest. Note the palm of the hand to provide tension so the incision is over the iliac crest (a) so that the final scar is below the iliac crest (b, c).

connection with various items of clothing. The normal technique is to pull the skin upwards by depressing the soft tissues superior to the crest with the palm of the hand. This will allow an incision to be made directly over the crest of the ilium, but when the tension is released from the incision, it will lie 3–4 cm below the iliac crest (Fig. 51.13). The incision can be made directly through skin, subcutaneous tissue, Scarpa's fascia, any superficial rectus muscle, and down to the iliac crest. If one approaches the iliac crest directly, virtually no major muscle attachments are encountered. Incisions from the lateral side will

entail sectioning of the gluteal muscles. There is a number of superficial sensory nerves passing over the crest of the ridge, and in particular, the iliohypogastric nerve is normally at risk and often leaves patients with a palm-sized area of paresthesia on the lateral side of the iliac crest. The lateral cutaneous nerve of the thigh is normally placed more anterior.

Once the crest has been identified, the incision can be taken down to the bone itself and subperiosteal elevation can be commenced. In most cases, it is advisable to formally identify the anterior limit of the iliac crest and the origin of the inguinal ligament. As one goes more posteriorly, the tubercle is identified some 5–6 cm posterior to the anterior spine, and this is the most productive site for harvesting bone marrow (Fig. 51.14). If medial cortex of the ilium is required, then the subperiosteal dissection only needs to be continued on the medial side, and this strips away easily, since the iliacus muscle is not attached to the ilium superiorly, and there are no other muscle attachments or vital structures in this area. On the lateral side, however, the gluteal muscles are attached, and if full-thickness grafts are required, these will need to be stripped away resulting in short-term discomfort and stiffness.

To obtain marrow

This is normally obtained directly over the iliac tubercle, since this is the widest point of the ilium (some 5–6 cm posterior to the anterior iliac spine), although it can be obtained elsewhere in the ilium. A lid from the superior surface of the iliac crest is normally raised, centered over the tubercle. This can take the form of bone cuts anteriorly and posteriorly joined by a cut directly along the middle of the iliac crest to

Fig. 51.14 The tubercle (with dotted line over it) has the largest source of cancellous bone in the anterior ilium. It is 5–6 cm posterior to the anterior superior iliac spine.

raise small trap doors medially and laterally to expose the crest. If this is to be carried out, periosteum should remain attached laterally and medially so that these trap doors do not become totally free grafts. On completion of the procedure, these trap doors can be replaced. Cuts can be made with chisels, drills, or reciprocating saw. Alternatively, a single coffin lid type bone flap can be raised based either laterally or medially; again, periosteum should be retained at the site of the hinge so that it does not become a totally free flap (Fig. 51.15). Marrow is now exposed and can be curetted with suitable size curettes. One should start with the largest curette possible to fit between the lateral and medial plates of bone, and curettage may need to be quite aggressive. As one descends inferiorly, the size of curette may need to be decreased to fit between the lateral and medial plates. Care should be taken to attempt to avoid perforation, which normally occurs on the medial side. Small perforations can be accepted, the main risk is to underlying structures. Amounts vary, but 20–30 ml of compressed bone can normally be obtained from the average ilium. If necessary, both left and right sides can be used at a single operation. On completion of taking the marrow, the bone flap can be replaced and is normally self-retaining, though if required a suture can be placed through holes drilled in the bone. The marrow that is taken is normally placed in a container and covered with a moist gauze. Closure is in layers, starting with the periosteum and including Scarpa's fascia, and the wound does not normally need to be drained.

Corticocancellous blocks

The anterior iliac crest lends itself to taking corticocancellous blocks for more extensive reconstruction. If bone is to be taken from the medial surface of the iliac crest, then the periosteum and iliacus muscle are retracted with an abdominal retractor and the area of bone to be taken is outlined with a drill or reciprocating saw. The inferior margin of the bone to be taken only needs to be outlined through the cortex. The bone to be taken will generally include a portion of the iliac crest, and so the anterior and posterior cuts are made through approximately 50% of the iliac crest, and are then joined along the center of the iliac crest. The block of bone is then removed utilizing appropriate sized straight and curved chisels. In this way, copious amounts of bone can be removed in strips approximately 2–3 cm in width (Fig. 51.16). Strips wider than this tend to fracture. On completion, a suction drain is often placed over the harvesting site and left in place for 24–36 hours, or until drainage is less than 20 ml in 8 hours.

For major mandibular reconstruction, through and through corticocancellous blocks can be taken to include both lateral and medial cortices of the ilium, leaving a hole in the ilium. For this, extensive periosteal stripping needs to take place on both the medial and lateral surfaces to identify the iliac ligament,

Fig. 51.15 The variety of “trapdoor” and “coffin lid” type incisions, based laterally and medially, that are used to access the cancellous bone in the iliac tubercle.

Fig. 51.16 Corticocancellous strips of bone taken from the medial surface of the ilium.

anterior notch, and posteriorly towards the sacroiliac joint, which should not be entered. This defines the area of bone that can be taken. A template is often helpful depicting the shape of bone required, and this can be made from sterilized aluminum from a soft drink can. A flexible plastic surgical ruler can also be used. The easiest way to take the size of block required is to remove the associated iliac crest. If this is carried out, the iliac crest is removed as a single block, starting at least 1 cm posterior to the anterior superior iliac spine, to prevent its fracture, and proceeding posteriorly, 1 cm posterior to the posterior limit of the block. In this way, the crest can be removed and then wired or plated back in place once the

block has taken, and it will mortise into place nicely (Fig. 51.17). The corticocancellous full-thickness block can now be taken from above, with appropriate drills and saws. However, this does weaken the crest considerably, and may cause more postoperative morbidity. A preferable technique is to leave the iliac crest intact and to take the full-thickness portion of bone from below it (Fig. 51.18). These blocks are normally taken from the ipsilateral side of the patient, since the curvature is more appropriate to the mandible on the same side. If the crest is to be left intact, the approach is normally from the medial side where access is better, and is with a combination of reciprocal saw, oscillating saw, and drills. Once the block has been taken, some marrow can usually be obtained from around the edges, and is often helpful in the reconstruction to augment any defects.

The wound is normally drained with a suction drain and closure is then carried out in the normal way in layers. Long-term postoperative radiographs show that a corticocancellous block less than 2–3 cm will normally form new bone, whereas a larger one will leave a permanent defect in the ilium, although herniation does not occur (Fig. 51.19). However, if it

Fig. 51.17 (a, b) The technique of removing and rewiring the iliac crest to remove corticocancellous blocks of bone from below the crest, similar to the one seen in Fig. 51.4. (c) By using oscillating and reciprocating saws the crest can often be left intact for greater strength and decreased morbidity.

Fig. 51.18 The residual defect seen clinically.

is felt that it may be necessary to go back again to obtain more bone for subsequent reconstructions, it is not necessary to drain the site and in this case blood will accumulate in the defect and, if periosteum is intact, may form new bone that can be reharvested. This does, however, run the risk of extensive hematoma formation. A drain placed in a full-thickness donor site will normally drain a total of 100–200 ml of blood over 24–36 hours, and should be removed when drainage is below 20 ml in 8 hours. It is often helpful not to remove the drain until the patient has been mobilized, since assuming the upright posture can result in drainage of additional pockets of fluid.

Large corticocancellous grafts can be harvested in this way and a single block can include the body, ascending ramus, and even the condyle (see Fig. 51.7). The block obtained is normally shaped to fit the defect, and the cortex is thinned with a large bur and perforated to aid revascularization.

Posterior iliac crest

The posterior iliac crest has been advocated for obtaining bone for orthopedic procedures on the spine, but has also been suggested as a donor site for oral and maxillofacial surgical procedures.²⁷ Large amounts of marrow can be obtained (up to 40–50 ml of compressed marrow from each side), and small corticocancellous blocks can be obtained. The incision runs over the posterior iliac crest which can normally be palpated and starts approximately 3 cm lateral to the midline of the center of the spine, and as it goes superiorly, it moves laterally at about 15° to stay over the posterior iliac crest. The incision is deepened

Fig. 51.19 Radiograph of ilium 6 months post iliac crest graft showing residual asymptomatic defect.

down to the posterior crest, and no major structures are identified en route, except for the cluneal nerves, which do supply the ipsilateral skin around the anus itself and can give an area of paresthesia in this region. They can normally be retracted with the soft tissues.

The main complications of this technique are possible involvement of the sacroiliac joint, and postoperative back discomfort, which is often difficult to separate from any other cause of back pain. The main disadvantage of this technique, however, is that it is necessary to turn the patient over to obtain the bone, and this is technically difficult to perform (particularly on an obese patient), and may provide some difficulties in staging the procedure and keeping the recipient site sterile if it has been opened first. This wound does not normally need to be drained.

Tibia

The proximal end of the tibia has been advocated as a donor site for bone marrow, and small pieces of cortex only. Both lateral²⁸ and medial²⁹ approaches have been suggested. Both approaches are fairly straightforward. In the lateral approach, Gerdy's tubercle is identified and the incision carried down at 45° from it inferiorly for 2–3 cm and by blunt dissection can be carried straight down to the tibia. There are normally no major vessels or nerves encountered in this approach. Similarly, the medial approach entails a

vertical incision 1 cm medial to the anterior prominence of the tibia, and blunt dissection down to the tibia itself. The major complication from tibial bone harvest is tibial plateau fracture, which has been noted in connection with maxillofacial procedures, and can be a major long-term complication. For this reason, no bone should be taken (either cortical or cancellous) within 1 cm of the tibial plateau.

An oval window is made through the cortical bone of the tibia. This is normally approximately 2 cm by 1 cm, and is performed with a drill (Fig. 51.20). It should be oval without sharp edges to prevent any stress fractures developing from the corners of the window. The window can either be removed completely (and used as a cortical graft), or replaced at the end of the procedure, or swung out on attached periosteum, either laterally or medially. Once through the cortical bone, marrow can be curetted with ease,

Fig. 51.20 Oval window in the lateral tibia and bone removed.

although one should stay at least 1 cm below the plateau. Twenty milliliters of compressed marrow can often be obtained from the tibia, although it is always of a more fatty appearance than marrow from the hip. Nevertheless, it does perform well clinically when used in a carrier tray for mandibular reconstruction.

The wound is normally repaired in layers. Post-operative weightbearing precautions vary widely. In practice, the medial epicondyle of the tibia takes approximately 55% of the body weight, whilst the lateral epicondyle takes approximately 45% of the weight. Therefore, one would assume that tibial plateau fractures were more likely to happen from the medial approach, and more weightbearing precautions may need to be taken. Both in orthopedic and oral and maxillofacial surgery, however, weightbearing precautions following tibial grafting vary widely, from some centers advocating no precautions at all and letting the patient walk immediately, to those that provide a cane, or walker, or even instructing the patient not to be weightbearing on the knee for 3–4 weeks. In practice, the complication rate does not seem to vary, so it would appear that in most cases, minimal weightbearing precautions are necessary.

Bone-containing microvascular free flaps

An alternative technique for reconstruction following segmental resection is with a microvascular free flap. Possible donor sites include the fibula (Fig. 51.21),^{30–32} iliac crest³³ or scapula.³⁴ The radius was previously

Fig. 51.21 (a) Mandibular reconstruction including the condyle with a segmental free fibula bone graft. (b) It was subsequently secondarily restored with osseointegrated implants following thinning of the intraoral soft tissue component of the graft.

used for this purpose, but it is associated with a high incidence of subsequent fracture of the radius, and this technique is rarely employed today.³⁵ To be successful, there need to be suitable feeding vessels; these would normally be the facial vessels, but, if necessary, other vessels can be used. If the length of the vascular pedicle is in doubt, intervening vein grafts can be used to enable successful anastomosis. Conceptually, the advantages of a microvascular reconstruction are:⁷

- soft tissue can be transferred at the same time as the bone;
- all procedures can be performed primarily;
- this technique can be used in areas of poor vascularity, including previous radiation therapy;
- success rate remains high for longer-span reconstructions.

The disadvantages of reconstruction with a vascularized graft may include:

- The bulk of soft tissue transferred with the bone is often too thick for subsequent prosthodontic reconstruction and subsequent procedures must be carried out to thin the soft tissues.
- The bulk of bone is often suboptimal for later implant insertion, though the initial graft can be augmented or modified in some way to make implant insertion more feasible. For example, a

Fig. 51.22 Cross-section of a fibula showing the thick cortical bone with a smaller area of predominately yellow, fatty, marrow with an overall diameter of 10–12 mm.

fibular bone graft can be doubled over on itself to create a double thickness (a single fibula is approximately 10–12 mm in thickness) (Fig. 51.22) to ensure that more bone is present for implant insertion.

Reconstruction involving the mandibular condyle

When the condyle is resected as part of a surgical procedure, another layer of complexity is added to the reconstructive process. The mandibular condyle is a complex articulation involving both hinge and sliding mechanisms with an intervening meniscus and muscle attachment to the condyle and meniscus themselves. It is not possible to reconstruct all elements of the joint, and therefore any reconstruction must be suboptimal as far as function is concerned. Nevertheless, a reasonable joint reconstruction is possible.

Rib grafting

An autogenous rib, including a 1–2 mm of costal cartilage, has been used for many years to reconstruct the condyle, and long-term follow-up is available showing very satisfactory long-term remodeling of the rib into a very acceptable condyle (Fig. 51.23).^{36–38} In younger patients the rib appears to grow in harmony with the rest of the face, although cases of overgrowth of the reconstructed condyle have been reported, and a growth-arresting procedure is occasionally necessary. This usually consists of a minimal arthroplasty to remove the active condylar and subchondral region.

Alloplastic condyle

A number of alloplastic condyles have come and gone over the years, and a small number are still available.^{39,40} In general, the smaller the joint to be replaced, the more difficult it is to make a successful alloplastic joint and the more risks and complications appear to

Fig. 51.23 A rib with a cap of costochondral cartilage (a) used to reconstruct the right condyle (b). Appearance 20 years later showing extensive remodeling (c). The patient continues to have good facial symmetry and normal mandibular movements.

be associated with the process. Therefore, for the hip joint, good long-term success is reported, but as the joints get smaller, the reconstruction becomes more difficult. Additionally, the mandibular condyle, with its combination of hinge and sliding motion, has proved extremely difficult to reproduce in an alloplastic replacement. The indication for alloplastic replacement in most cases is for function rather than for pain. Most replacements include both the glenoid fossa and the condyle, and it is generally recommended that both are placed at the same time. In some cases, the alloplastic joint is a stock replacement, whilst in other cases it is custom made from a computed tomography (CT)-generated three-dimensional model. Most implants are constructed of titanium with or without an element of high impact polymer (Fig. 51.24). Long-term results from these implants are generally not currently available.

Replacement with a metatarsal

Condylar reconstruction with the second or third metatarsal bone has been reported with some success, but long-term results are not available, and in some cases the deformity to the foot has been felt to be unacceptable, with collapse of the remaining tarsal bones and a subsequent discrepancy in foot and shoe size.⁴¹ Nevertheless, the size of a metatarsal is very compatible with that of a condyle, and surgically it makes an excellent replacement.

Sternoclavicular joint

A full-thickness, or split-thickness, sternoclavicular joint has been used as a condylar replacement, with or without an attached portion of the sternum to replace the glenoid fossa.^{42,43} The advantages are said to be that the joint is of the appropriate size and it is a joint with a meniscus between the joint surfaces. Disadvantages include the risk of pneumothorax as well as damage to the nerves and vessels at the root of the neck, particularly the brachial plexus.

Fig. 51.24 (a) A custom-made TMJ prosthesis constructed on a three-dimensional model. (b) On surgical placement.

Microvascular reconstruction of the condyle

Microvascular reconstruction of the condyle is possible using a fibula.⁴⁴ The fibular bone is normally rounded off to fit in the glenoid fossa, and a temporalis fascia flap can be placed to separate the fibula from the glenoid fossa, since there is no cartilage on the surface of the fibula. This method of reconstruction is obviously more complex, more time consuming, and associated with a longer hospital stay, but can be used, particularly for patients who have received preoperative radiation therapy.

Staged techniques

Reconstruction of the mandibular condyle, ramus of mandible, and body of mandible is associated with particular problems. Primary reconstruction with a non-vascularized bone graft is associated with a high failure rate, normally from wound breakdown in the mandibular body section associated with thin intraoral mucosa and wound contamination. Breakdown rarely occurs over the ascending ramus of the mandible or condyle area since these are not normally contaminated by saliva and have covering from the medial pterygoid muscle medially and the masseter muscle laterally, providing a bulk of vascularized soft tissue. However, secondary reconstruction, even carried out after 6 or 8 weeks, is problematic, since it is difficult to gain secondary access to the glenoid fossa to insert a non-vascularized graft, such as a rib graft secondarily. Although temporary alloplastic condyles are available, they are sometimes difficult to insert, and are very often difficult to remove, since fibrosis often forms around the condyle head making subsequent removal and replacement with a rib graft difficult (Fig. 51.25). For this reason, a staged reconstruction has been advocated.⁸ In this technique, following resection, immediate reconstruction of the condyle and ascending ramus is carried out with a rib graft (Fig. 51.26). This maintains the articulation of the glenoid fossa, and generally survives because of the vascularity of the surrounding musculature and the adequacy of the intraoral closure. Temporary reconstruction of the body of the mandible is with a titanium reconstruction plate. Some 6–8 weeks later, the body of the mandible is then reconstructed from an extraoral approach, as detailed previously, using corticocancellous blocks from the ilium. In this way, the reconstruction of both the condyle and the body of the mandible is optimized, and high success rates have been reported.

Radiation therapy

Radiation therapy to the mandibular area complicates reconstruction. Radiation therapy causes an endarteritis, which decreases the vascularity, cellularity, and

Fig. 51.25 A temporary alloplastic titanium condyle attached to a reconstruction plate. Removal of the condyle for secondary autogenous reconstruction can be difficult due to fibrosis and scarring.

Fig. 51.26 A rib graft attached to a reconstruction plate for primary reconstruction of the condyle. The mandibular body will be reconstructed secondarily with a corticocancellous block graft from the iliac crest.

tissue oxygenation of the associated tissues. The endarteritis and hypocellularity usually commence some 3–4 months following the radiation therapy and are continuous in nature; they are well established by 6 months. The tendency is for the endarteritis and hypocellularity to become more pronounced with time. There is no evidence that it is a reversible process. There is, however, a so-called “golden window” up to 3–4 months following radiation therapy during

which bone grafting can be carried out in a normal way. From a practical point of view, the immediate local complications of radiation therapy will often preclude the bone graft during the first 6 weeks following radiation therapy, while the mucositis, etc. resolve, and therefore the “golden window” is really from 6 weeks following radiation therapy to 3–4 months following radiation therapy. After this time, the failure rate from non-vascularized bone grafts is generally felt to be unacceptably high due to the avascular tissue bed. If it is intended to carry out mandibular reconstruction in an area that has received more than 55 Gy of radiation, it should either be with a vascularized graft⁴⁵ or possibly following a course of hyperbaric oxygen therapy to increase the vascularity and cellularity of the tissue bed. There is good evidence that hyperbaric oxygen (30–40 dives at 2.4 atmospheres pressure for approximately 90 minutes) can produce a tissue bed in which a non-vascularized bone graft can survive.^{46,47} There is no evidence that hyperbaric oxygen can reactivate a dormant malignant tumor or cause recurrence of a dormant malignant tumor. If the bone graft takes satisfactorily, implants can subsequently be inserted.⁴⁸

In the case of a vascularized graft, if previous radiation therapy has been given, although the nature of the recipient vessels may be changed and they may have a greater element of fibrosis, successful

anastomosis, and re-establishment of vascularity are possible.

If a microvascular graft is inserted immediately and then radiation therapy given subsequently, then the microvascular graft will be affected by radiation therapy just like all the other tissues, and subsequently implant insertion may be compromised. If, however, the microvascular graft is inserted after radiation therapy, then it will not have been subjected to irradiation, and, providing the vascularity is adequate, implants can be inserted with safety even though the surrounding tissues may have been irradiated.

Bisphosphonate therapy

The use of medically administered bisphosphonates, either intravenously, in the management of bony metastases in malignancies such as multiple myeloma, breast cancer, and prostate cancer, or oral forms of bisphosphonates, used mainly for the management of postmenopausal osteoporosis, have been shown to decrease bone turnover, initially by inhibiting osteoclast function and later also inhibiting osteoblast function. Although of potential value in some conditions where bone turnover may be excessive, their use has compromised some bone reconstruction and grafting procedures; if a patient is taking one of these medications, its possible effect on any bone graft or mandibular reconstruction should be evaluated.⁴⁹ With the intravenous forms, discontinuing the medication normally has no effect since the bisphosphonate continues to be excreted by the bone on to its surface for up to 10 years. However, with the oral forms, it is possible that discontinuing the medication for 6–9 months will allow bone turnover to recover, and if the bisphosphonates are not recommenced for 6 months after any bone grafting, this may allow the graft to incorporate and remodel to a certain extent. Bisphosphonate administration will slow down, or prevent, bone remodeling.

Chapter 52

Tissue Engineering and Reconstruction

Henning Schliephake

The aim of tissue engineering is the enhancement of tissue repair by regeneration of local tissues adjacent to a defect and/or *ex vivo* generation of artificial tissue hybrids that can act like grafted tissue in the defect area after implantation. In general there are two major avenues through which this aim is approached: growth factors that mediate tissue proliferation and differentiation are administered to accomplish defect repair, or cells – in particular adult stem cells generated from the tissue to be replaced and expanded *in vitro* – are implanted into the defect to form new tissue. Both approaches have been extensively explored in experimental and preclinical settings. Clinical applications are, however, rather sparse due to a number of biological and technical issues that are associated with human use. This chapter outlines present applications of tissue engineering techniques in maxillofacial reconstruction.

Introduction

Tissue engineering in reconstructive surgery encompasses all measures that are suitable to enhance tissue regeneration *in vivo* in order to obviate the need for autogenous grafts. The term tissue engineering has been defined as “the application of the principles and

methods of engineering and the life sciences towards fundamental understanding of structure/functional relationships in tissues...and the development of biological substitutes to restore, maintain, or improve tissue functions”.¹ Initially, activities in this area were mainly focused on cell-based approaches aiming at the generation of tissue-like constructs by combining *ex vivo* expanded cell populations with various types of scaffolds. Today, the field of tissue engineering has expanded tremendously, in that not only cells and scaffolds but also growth factors, controlled release carriers, engineering of biomaterials and many other areas of basic and applied research are considered to be part of the field of tissue engineering.

The interest and attention that this rapidly developing area has received are based on the vision that the growing understanding of tissue healing and the achievements of biotechnology will be of profound therapeutic relevance. In clinical reality, reconstructive surgery has arrived at a standard of care that allows for repair and restoration of the vast majority of patients with established techniques; the challenge of tissue engineering in clinical treatment is the reduction of surgical morbidity by the application of biological signals or bio-artificial components cultivated from the patient's own cells, that can replace the lost body part or accomplish its repair without the need for autogenous tissue transfer.

During the past decade, the principles of tissue engineering have also been applied to oral and maxillofacial surgery. Bone tissue is a major focus, but oral mucosa, cartilage, and salivary glands have also received some attention. All approaches in tissue engineering have to consider basic principles of tissue biology and the specific requirements of those tissues that should be replaced or repaired. These are the conditions for cell differentiation and morphological organization as well as the interactions between different types of cells necessary for repair. They form the basis for successful tissue engineering in reconstructive surgery.

Basic principles of tissue engineering

Regeneration of tissues is a complex and highly orchestrated process that, nevertheless, proceeds along a rather uniform pathway including the three well known steps of inflammation, proliferation, and remodeling. During this process biological signals accomplish the increase in cell numbers that fill the defect or cover the wound. At the same time, specialization of the newly formed tissue occurs through morphogenic signals which induce the tissue specific differentiation. Most of the biological signals that increase both proliferation and induce differentiation of cells are conveyed by polypeptide growth factors. These growth factors are supplied by either local cells or by circulating cells and blood components such as macrophages and platelets. Moreover, growth factors originate from the extracellular matrix (ECM) where they are stored and released during tissue remodeling and repair. During this process, the extracellular matrix serves an additional purpose by providing a three-dimensional scaffold for the migration of cells and their arrangement in a tissue-specific manner. In this way, cells, signaling molecules, and the ECM are closely linked and form the basis of tissue homeostasis and regeneration *in vivo*.

When these three components are transferred to the *in vitro* environment of tissue-engineered constructs, the extracellular matrix is replaced by synthetic or natural scaffolds which are used to accommodate and arrange the cells in a three-dimensional fashion. The triad of cells, signals, and scaffolds thus makes up the "classic" tissue engineering triad. However, beyond these three components, angiogenesis and vascularization play an important role in cellular behavior and tissue repair, not only because blood supply is necessary for cell survival and development, but also because vessels provide a reservoir of undifferentiated perivascular cells that are recruited during tissue repair. Therefore, it is entirely the combination of at least four major factors that contribute to tissue regeneration and, thus, to the success of tissue engineering approaches: cells, growth factors, scaffolds, and vascularization.

Although the role of individual factors during tissue generation and repair is quite well researched, many details of this process are still unclear. In particular, the key features for the determination of tissue and organ morphology that result in the creation of the tissue-specific complex micro-architecture of vessels, stroma, and specialized cells, as well as a specific organ shape, are not completely understood. Additionally, the role of biological or mechanical interactions between the newly formed cells and their micro-environment has not yet been analyzed to an extent that would allow for the simulation of *in vivo* conditions of tissue regeneration in an *ex vivo* environment. As neither the technology for the cultivation

of vascularized cell-seeded scaffolds nor the possibility to provide *in vivo* conditions for *ex vivo* tissue formation are available yet, all tissue engineering endeavors have to rely on the contribution of the *in vivo* milieu of the local tissue at the site of implantation.

Most of the tissue engineering strategies have used only two of the four basic components yet. In general, the approaches can be grossly divided into cell-based approaches and those using growth factors. Cell-based devices employ specialized cells and scaffolds that are implanted into the recipient site. Ideally, these cells are autogenous cells that have been obtained from the tissue to be replaced by a minimally invasive surgical procedure with negligible morbidity. The initially small number of cells is expanded *ex vivo* and seeded into scaffolds to obtain a biohybrid construct that provides specialized cells in a three-dimensional arrangement. After implantation of these constructs into the *in vivo* environment, the seeded cells are supposed to continue with proliferation and differentiation, thus forming the desired tissue within the implanted scaffold. This approach relies on the host tissue to contribute the necessary cytokines that provide appropriate signals for proliferation, final differentiation, and tissue formation through the cells within the scaffolds as well as vascularization of the scaffolds to keep the implanted cells alive.

Approaches that are based on growth factors apply them in scaffold materials which serve two purposes. On the one hand, scaffolds act as carriers for the signaling molecules, providing a three-dimensional structure from which the growth factors are released to recruit specialized cells required for tissue repair. On the other hand, they function as space-making devices which prevent soft tissue collapse and provide room for the newly formed tissue to penetrate and unfold. These approaches rely on the host tissue to supply both vascularization and the necessary population of either specialized cells or undifferentiated cells that can be induced into the required type of tissue by the applied growth factor.

Both strategies are still struggling with a number of fundamental issues. Cell-based approaches deal with questions of *in vitro* conditions for tissue-specific expansion, seeding, and cultivation, as well as cell survival and function *in vivo*, while strategies for the application of growth factors focus on dosage and controlled release as well as possible interactions with the carrier material.

In order to overcome some of the problems of cell-based devices, combinations of scaffolds, cells, and growth factors have been explored. In the majority of cases recombinant cells have been employed which were designed to produce the desired growth factor after implantation *in vivo* to enhance vascularization and to avoid dedifferentiation of the implanted cells under adverse conditions of initial wound healing with decreased oxygen supply, decreased pH, and

impaired metabolic supply. Some approaches have used scaffolds directly loaded with growth factors in combination with cells. The results of all these experiments have shown that the combined use of cells, growth factors, and scaffolds may hold some promise for the improvement of the functionality of tissue-engineered biohybrid scaffolds.

Biomaterials

Biomaterial tissue interaction

Biomaterials are implanted to improve tissue function or to enhance tissue repair. In reconstructive surgery they are used to fill defects, to bridge gaps, or to cover wounds. They may function as scaffolds for tissue ingrowth and thereby enhance tissue regeneration or act as stabilizing devices to fix or join loose tissue parts. There is a large variety of different materials that are used and their characteristics differ according to the mechanical and biological requirements of their application. The same holds true for interactions between biomaterials and recipient tissues. They vary across the implantation period and their nature depends very much on whether the material is loaded or unloaded and whether it is intended to stay permanently in the body or is meant to degrade and disappear. Early events which occur immediately after implantation or during early stages of healing differ from those that can be seen after tissue integration. While the latter depend very much on the chemical nature of the material and its behavior in terms of degradation and material release, the former are considered to be affected mostly by physical surface characteristics.

When a biomaterial is inserted into living tissues, a cascade of events is initiated that starts with the adsorption of biomolecules to the material's surface. Important characteristics for the immediate interaction with the *in vivo* environment are surface charge and surface energy of the material. An increase in surface energy improves the wettability of the material surface facilitating the adsorption of serum proteins and other biomolecules such as fibronectin.^{2,3} This initial wetting, also referred to as flash spread, that is accompanied by the adsorption of biomolecules, is one of the most important preconditions for cells to become attached to the material surface and to establish tissue contact with the biomaterial. Surface energy and surface charge themselves depend on the material composition and on the surface structure. Metals and mineralized materials commonly have a negative surface charge under physiological conditions due to the presence of oxide molecules on their surface. This results in the adsorption of positively charged molecules to the biomaterial surface (Figs 52.1 and 51.2).

Surface energy varies considerably between different material classes. While polymers such as poly-

lactic acid (PLA) have a rather low surface energy and hence a rather hydrophobic surface characteristic, the higher surface energy of many metals and ceramics in particular renders these surfaces hydrophilic which can enhance tissue integration from the material side. Hydrophobic interactions between a material surface and adsorbed proteins can go along with stronger interacting forces between the surface and the protein, facilitating critical conformational changes of the adsorbed molecule, which may result in decreased functional activity of the respective protein. As hydrophilic surfaces are associated with less conformational changes of the adsorbed proteins, increased hydrophilicity can support the cascade of cellular events involved in the attachment, migration, and tissue-specific differentiation of cells.

Another feature that affects the interaction between biomaterials and living tissues is the surface texture. Microrough surfaces have been shown to affect cellular attachment and differentiation. Several factors are considered to contribute to the improved performance of these surface modifications when compared to non-structured surfaces. One positive effect of microstructured surfaces comes through the increase in surface energy that is associated with increased surface roughness and hence improved wettability.⁴ Another positive effect on cellular behavior is mediated through the microtexture itself. This has been

Fig. 52.1 Scanning electron microscope (SEM) image of the crystalline structure of the surface of a hydroxylapatite scaffold.

Fig. 52.2 Surface covered by proteins adsorbed from cell culture medium.

shown in surface modifications of titanium implants. Different degrees of surface roughness have been shown to modify cellular production of receptors that mediate adhesion to titanium surfaces.⁵ Moreover, increased secretion of molecules indicating osteogenic differentiation of cells in contact with the microtextured surface as well as enhanced production of cytokines involved in bone formation has been reported *in vitro*.^{6,7}

Surface characteristics play an important role, not only *in vivo* for the biomaterial tissue interaction, but also in the *in vitro* environment for tissue engineering purposes, as cellular attachment, migration, and differentiation are key issues in the construction of biohybrid scaffolds. In this way material science in biotechnology can contribute substantially to the success of tissue engineering by optimizing immediate and late interactions both between seeded cells *in vitro* and living tissues after implantation *in vivo*.

Scaffolds

Scaffolds are used as carriers for cells and/or growth factors. Ideally, they provide a three-dimensional structure of interconnecting porosity that supports the ingrowth of vessels to supply the implanted cells and/or allows for the release and diffusion of biological signals which then enhance ingrowth of undifferentiated cells through a chemotactic gradient and accomplish final tissue-specific differentiation.

In general, the plethora of materials that are used as scaffolds can be divided into organic and inorganic materials. Organic materials may originate from natural precursors such as collagen, chitosan, or silk (Figs 52.3 and 52.4), or can be produced from synthetic

polymers such as PLA (Fig. 52.5) and polyglycolic acid (PGA). Inorganic materials commonly consist of metals, alloys, or mineral compositions. Mineral compositions may vary considerably containing mixtures of calcium, sodium, potassium, silicates, magnesium, aluminum, zirconia, carbonates, or phosphates. Mineralized scaffolds may be purely synthetic or derived from natural precursors such as corals, algae, or bovine bone (Figs 52.6 and 52.7).

A critical feature for the performance of scaffolds *in vivo* is the degree of porosity. Only scaffolds with interconnecting pores will become vascularized and completely penetrated by ingrowing tissue. Pore sizes are divided into micropores (<10 μ m) and macropores (>50–60 μ m). The former can enhance the retention of growth factors soaked into the material or have an effect on cell attachment, migration, and differentiation, whereas the latter play an important role for the nature of the ingrowing tissue. While pores of 50 μ m allow for the ingrowth of individual

cells, vascular ingrowth can be seen at pore sizes $>150\mu\text{m}$ and ingrowth of mineralized bone requires a pore size of $250\mu\text{m}$.

There is always a link between the scaffold material and the scaffold structure in that the strength and the elasticity of the various materials allow only for limited variations in scaffold geometry. Organic scaffolds of natural origin, such as chitosan and silk that are produced by electrospinning, commonly form a porous textile structure.^{8–10} The same holds true for polymer fibers that may be also produced as non-woven fleeces. They all have in common a thin and elastic fibrous scaffold structure that allows for cell attachment but may impair spreading of cells that require a flat surface structure (Fig. 52.8). The advantage of this type of scaffold, however, is the wide open pore space which enhances metabolic exchange and tissue penetration. Conversely, organic scaffolds become very brittle if their structural elements fall short of a minimum thickness. Metallic scaffolds can be produced as open porous three-dimensional structures by selective laser melting. However, the pore size of these types of scaffolds is far above the micrometer range. Mineralized scaffolds from synthetic materials are commonly produced from slurry or powders that are sintered in the presence of a foaming agent such as H_2O_2 or with the addition of NaCl or sugar as porogens that are subsequently removed during sintering or leaching. An alternative

route is the imbibition of organic scaffolds of defined geometry with calcium phosphate slurry and subsequent removal of the organic components during sintering.¹¹ The disadvantage of this technique is the fact that the resulting bubbles and void spaces that make up the pore spaces are not necessarily interconnected, which impairs tissue penetration and complete integration (Fig. 52.9). Mineralized scaffolds from natural precursors so far are the only ones that can provide a truly interconnecting open porous structure at the micrometer range.

For *in vitro* fabrication of biohybrid constructs, the structure and the nature of the scaffold material also have an impact on the morphology and the behavior of the seeded cells, in that the shape of the pore walls and the geometry of the scaffold components affect the attachment, proliferation, and migration of the cells. However, as the scaffold structure is closely linked to the scaffold material, the effect on cellular behavior, such as proliferation and differentiation, is always a combined effect of both surface morphology and material composition.

Biofunctionalization

The fact that the initial interactions of biomaterials with their host tissues are based on the adsorption of biomolecules from the *in vivo* milieu on the material surface has promoted the idea of enhancing the integration of these materials by modifying the surface conditions either by enhancing adsorption of these molecules *in vivo* or by activating biomaterial surfaces with biologically active molecules (BAMs). The strategies vary from altering the physical characteristics

through increased surface roughness to physico-chemical and/or chemical modification.¹² Many of these approaches have been used with metal surfaces, namely endosseous implants made of titanium or titanium alloys.^{13–16} Although metal implants do not yet play a substantial role in tissue engineering, measures to enhance peri-implant bone healing next to these implants fall into the realm of tissue engineering and the technology developed is also applicable to many other biomaterials used in this field.

Chemical modifications are probably the most promising approaches to enhance tissue integration and to modify peri-implant tissue reactions. Among these, strategies using organic chemistry to anchor biologically active molecules on the scaffold surface are particularly attractive as the critical process of cellular attachment could be short cut or even tailored to specific tissue requirements. In this way, the process of tissue integration could be considerably accelerated by placing a selected pattern of signals on the biomaterial surface. For these applications proteins or peptides involved in cell attachment and cell communication are of particular interest.

Key molecules for cell attachment and migration of cells are RGD peptides (a sequence of three amino acids Arg-Lys-Asp). Their biological effect is mediated through binding to integrin receptors on the cell surface.¹⁷ This activates a cytoplasmic signaling pathway that can alter cellular architecture or initiate cell migration and proliferation. A number of molecules from the ECM present different kinds of RGD motifs and bind to different integrin subunits. Collagen, for example, binds to $\alpha_2\beta_1$ units, while RGD motifs of bone-specific proteins such as vitronectin, osteopontin, and osteoprotegerin bind to $\alpha_v\beta_3$ and $\alpha_v\beta_5$ receptors.^{18,19} The specificity required to address different integrin receptor subunits is based on more complex peptide sequences (RGDXYZ motifs) than the short core sequence of three amino acids.^{20–24} Specifically designed RGDXYZ motifs, thus, could mimic certain components of the native

ECM and could selectively direct a specific population of cells to the material surface. In this way, bio-functionalization of material surfaces using RGD sequences has been successfully accomplished with various scaffold designs of a large number of materials such as chitosan, silk, polylactic and polyglycolic acid, polyethylene glycol (PEG), and titanium.^{25–30} All reports had proven increased cell attachment, cell proliferation or enhanced *in vivo* tissue integration (Figs 52.10 and 52.11).

Besides providing a matrix for cell attachment and migration, many components of the ECM have a reservoir function for growth factors that are released during tissue repair. In bone tissue, for example, glycosaminoglycans play an important role in the storage and release of growth factors from the bone matrix during remodeling and regeneration of bone tissue. In order to mimic natural events such as ECM degradation and release of BAMs, the use of specific organic coatings that mimic the function of native ECM could elicit a targeted cellular reaction and enhance the integration of the biomaterial into a specific tissue. Strategies using this approach have been developed by employing biomimetic ECM-like synthetic polymers that contain biologically active molecules that are released through the activity of matrix metalloproteinases (MMPs)³¹ and by using components of the native ECM that can accumulate BAMs (Figs 52.12 and 52.13).^{32–34} The latter approach followed a self-organizing principle, according to which ECM components such as chondroitin sulfate assemble spontaneously with collagen in a near natural fashion and could accumulate BAMs. This would allow for a more specific or enhanced biomaterial tissue interaction.

Methods to immobilize BAMs on to biomaterial surfaces depend on the stability of the BAMs themselves, as well as their molecular weight and structure. In general, BAMs can be attached to the surface of biomaterials through adsorption, covalent binding, nanomechanical incorporation, and self-organizing

organic layers.¹² As many biomaterial surfaces carry a negative charge under *in vivo* conditions, macromolecules positively charged under these conditions could adsorb with great stability due to electrostatic interactions. This has been used by Ruiz-Taylor *et al.* for immobilization of poly(L-lysine) on titanium surfaces.³⁵ In this approach, poly(L-lysine) was not the BAM itself but was used as an anchor molecule for covalently coupled PEG chains and RGD groups. This coating has been reported to be highly promotive for cell adhesion due to the incorporated RGD motifs.³⁶ The self-organization principle of organic layers has been also applied for the immobilization of collagen together with proteoglycans and glycosaminoglycans, which are the most interesting candidates due to their interactive potential with respect to bone matrix assembly and binding of growth factors. Designed components derived thereof through methods of functional glycomics have been used in more advanced approaches of matrix engineering.^{37–39} In this way, biofunctionalization of material surfaces

can significantly enhance their function *in vitro* and *in vivo*, particularly when growth factors are anchored to the surface.

Application of growth factors

Growth factors

Growth factors are polypeptides of approximately 6–45 kD that act as signaling molecules for cellular communication. They play an important role in morphogenesis and repair of tissues and organs. Their range of activity varies considerably during embryogenesis, postnatal growth, and adulthood. During embryonic development, growth factors are involved in limb patterning and morphogenesis of many organs, while in postnatal life their role is restricted mainly to tissue regeneration and repair. The biological effect of an individual growth factor *in vivo* is modulated by a complex system of feedback loops, which involve other growth factors, enzymes, and binding proteins.

Growth factors have a complex three-dimensional structure that is made up of either a single polypeptide chain or two chains that are identical in homodimeric molecules and different in heterodimeric molecules. This complex structure allows for selective binding to specific receptors on the cell surface. Receptors are transmembranous proteins which undergo conformational changes upon binding of the growth factor. This activates intracellular phosphorylating enzymes, which induce an intracellular signaling pathway by aggregation of cofactors and other proteins that migrate to the nucleus. Together with other transcription factors they activate a set of genes, which then bring about the specific changes in cellular activity or phenotype.

The effect of growth factors on their target cells can be different. They can act as mitogens in that they enhance proliferation of certain cell types. Some growth factors are also morphogenic in that they change the phenotype of their target cells. Growth factors acting in an autocrine manner affect the secreting cell itself, whereas paracrine growth factors affect their neighboring cells. For some growth factors, an endocrine effect is assumed or established from elevated serum levels. Many growth factors are deposited in the ECM where they are released during matrix degradation and act as part of a complex network of signals with mutual effects during tissue remodeling and regeneration.

The therapeutic application of growth factors for the repair of damaged tissue is used to enhance the level of regeneration beyond the limit to which spontaneous tissue repair has been downregulated in postnatal life. Thus, defects that would otherwise not heal in life time (“critical size defects”) are intended to be repaired without the need for additional tissue transfer.

Fig. 52.12 SEM image of a titanium surface microstructured by sandblasting and etching.

Fig. 52.13 SEM image of a sandblasted/acid etched titanium surface coated with collagen and chondroitin sulfate (CS). The typical structure is visible in the collagen fibers.

Many growth and differentiation factors of different origins have been employed both in preclinical and clinical tissue repair. When single growth factors are intended for therapeutic application, recombinant growth factors are commonly used. Recombinant growth factors are identical to human growth factors with respect to amino acid sequences and three-dimensional structure. They are produced by either eukaryotic cells or bacteria (*Escherichia coli*) that have been transfected/transduced with the respective gene.

The majority of growth factors used in maxillofacial reconstruction are directed towards the repair of mesenchymal tissues. Some of them are also involved in the interaction between mesenchymal tissue and epithelium during mucosa repair. In particular, bone regeneration is a clinical focus of tissue engineering using growth factors. There are at least six growth factors involved in bone regeneration that have been used in maxillofacial reconstruction in a large number of animal models:

- platelet-derived growth factor (PDGF);^{40–42}
- basic fibroblast growth factor (bFGF);^{43–46}
- insulin-like growth factor (IGF);^{47–50}
- transforming growth factor beta (TGFβ);^{51–53}
- vascular endothelial growth factor (VEGF);^{54,55}
- bone morphogenetic proteins (BMPs).^{56–59}

PDGF is a dimeric protein of 30 kD with two different peptide chains (A and B) which combine to three isoforms of PDGF: two homodimeric forms (PDGF-AA and PDGF-BB) and one heterodimeric molecule (PDGF-AB). PDGF-AB and PDGF-BB are available systemically in the α-granules of platelets, whereas PDGF-AA is secreted locally by osteoblasts. *In vivo*, PDGF plays an important role in the recruitment of cells for the repair of mesenchymal tissues such as bone, cartilage, and connective tissue. The effect is predominantly mitogenic and chemotactic for precursor cells in that proliferation is stimulated, whereas differentiation into the specialized cells or tissue maturation is suppressed. Thus, PDGF acts as a key factor during early stages of regeneration and remodeling of these tissues by activating undifferentiated precursor cells, thereby increasing the number of inducible cells. However, it does not exert morphogenic effects by inducing differentiation into bone or cartilage tissue.

Basic fibroblast growth factor (bFGF, FGF2) is one of the 23 members of the fibroblast growth factor family. Native bFGF is bound to heparin and stored in the ECM. In bone tissue, biologically active bFGF is produced by osteoblasts and deposited in the bone matrix from where it is released during repair and remodeling. bFGF increases proliferation of mesenchymal cells and supports the differentiation of cartilage and bone cells. Moreover, it enhances the proliferation of endothelial cells and accelerates endochondral ossification presumably through

increased vascularization of the cartilage. Thus, bFGF acts as a mediator of bone formation at a rather early stage by increasing cell numbers and vascularization. It has no direct morphogenic effect on bone or cartilage tissue but has to be considered as one of the important adjuvant factors in this complex process.

IGFs are single-chain molecules that exist in two isoforms (IGF I and IGF II). In contrast to many other factors that act merely at a local level, IGFs also play a systemic role in postnatal growth. At a local level, IGFs act as survival factors that suppress cellular apoptosis and increase proliferation in a number of mesenchymal cell types such as osteoblasts, chondroblasts, and fibroblasts. Thereby, they support tissue regeneration and repair, albeit on a rather generic level.

TGFβ belongs to the TGF superfamily, a large family of more than 30 proteins that also includes the BMPs. TGFβ molecules are secreted as inactive molecules and activated by cleaving off N-terminal portions of the molecule. TGFβ molecules are multifunctional in that they affect adhesion, proliferation, and apoptosis of numerous cell types. They are involved in remodeling and repair of cartilage tissue and there is a dose-dependent effect on proliferation and differentiation of bone cells, in that high concentrations of TGFβ have a negative effect, whereas low concentrations increase cell numbers and maturation. TGFβ has a prominent role during soft tissue regeneration. It enhances matrix production and supports contraction of fibroblasts. In this way it can contribute to excessive scarring and the occurrence of radiogenic fibrosis.

VEGF is a homodimeric protein of which a number of modifications are known (VEGF A through F). The modifications differ in the length of the molecule. VEGFs are ubiquitous and play a central role in angiogenesis during tissue repair and inflammation. They are also important contributors to the occurrence of malignancies through the induction of neo-vascularization. Tissue hypoxia induces the production and secretion of VEGFs that interact with other growth factors to induce the development of a stable and defined system of mature vessels. VEGFs are involved in tissue regeneration and repair in more than one respect, as the newly formed vessels not only provide oxygen supply but also bring a perivascular population of undifferentiated precursor cells into the area of regeneration.

BMPs are homodimeric proteins of approximately 30 kD. Today, almost 30 proteins have been identified that belong to this family. During embryogenesis, BMPs play an almost universal role in the development of the body as they are involved in the organogenesis of kidney, lung, heart, central nervous system, eye, skin, and teeth. The most prominent effect of BMPs in postnatal life is the ability to induce the formation of bone tissue in ectopic sites, where otherwise no bone formation would occur. This ability is unique as it is able to recruit undifferentiated mesenchymal

cells through chemotaxis and induce the complete cascade of molecular events by the expression of bone-specific enzymes, proteins, and transcription factors such as alkaline phosphatase, osteocalcin, and Runx2 that are necessary to transform precursor cells into active osteoblasts that start to form bone.

The limited availability and the high costs of recombinant growth factors have prompted the search for alternatives, such as autogenous growth factors. One source of autogenous growth factors has been identified in concentrated platelet preparations (platelet-rich plasma, PRP). Platelets are among the first elements of the wound healing cascade to appear at a site of injury. They carry a variety of growth factors that are supposed to enhance wound closure and tissue repair. PRP, therefore, represents a mixture of autogenous growth factors with predominantly mitogenic activity suitable to initiate and accelerate tissue repair through an increase in cell proliferation. PRP is produced through a two-step centrifugation procedure that is subject to some variation with respect to the effect of platelet concentration and growth factor content. There are different centrifugation systems on the market and their ability to concentrate platelets varies between the factor 3 and 10. Additionally, there is considerable variation within the individual systems so that the reproducibility of the procedure has to be considered as low and requires individual quality control by platelet counts after centrifugation. Unfortunately, the amount of growth factors contained within each individual preparation of PRP is also not correlated with the number of platelets,⁶⁰ probably because the activation of platelets *ex vivo* and the release of growth factors from the alpha granules are not always reliable.

PRP contains all four growth factors: PDGF, TGF β , VEGF, and epithelial growth factor (EGF). The growth factors are deposited in the alpha granules from where they are released after the platelets have become attached to collagen fibers of the vessel wall or after exposure to thrombin. During therapeutic application of PRP, thrombin and calcium are added to release the growth factors from the platelets. *In vitro*, PRP enhances the proliferation of fibroblasts from the gingiva and the periodontal ligament. Proliferation of osteoprogenitor cells and osteoblasts is enhanced in a concentration-dependent manner; however, terminal osteogenic differentiation of progenitor cells is suppressed.⁶¹ Positive effects on the proliferation of epithelial cells have not been clearly shown. *In vivo*, PRP has been extensively tested in preclinical studies, mainly to explore the ability to enhance bone regeneration. PRP has been used in conjunction with both autogenous bone grafts and synthetic or natural carriers such as tricalcium phosphate (TCP), bovine bone mineral, collagen, and demineralized freeze-dried bone^{62–66} in peri-implant bone defects, sinus floor augmentations, onlay grafts, and segmental mandibular defects.^{67–71} The picture that arises from these studies is unclear because the number of studies

which failed to prove significant enhancement of bone regeneration is only slightly larger than the number of reports that could show a positive effect. The failure of PRP to prove a positive effect in preclinical studies has been explained by the inability to prepare appropriate amounts of PRP from animal blood with adequate quality.⁷² Unfortunately, the results derived from clinical studies are even less encouraging. A large number of clinical case reports or case series describe the use of PRP; however, there are only a few controlled trials.^{73–76} Only one of these studies has proven a significantly positive effect on bone regeneration in sinus lifts⁷⁶ while the remaining reports could not show a significant enhancement of bone formation in the augmented areas. One of the reasons for the failure of autogenous growth factors in PRP to show consistently positive clinical results may be the poor reproducibility with respect to platelet count and growth factor content of the individual preparations.

Recombinant growth factors have been tested as single growth factors and in combination with others merely with respect to their ability to enhance bone regeneration. In preclinical settings most of the human recombinant bone growth factors have not shown truly osteoinductive properties when they were tested as single factors. Only when used in conjunction with other growth factors did PDGF, bFGF, and IGF show enhancement of bone regeneration in peri-implant or periodontal regeneration models,^{41,43,48–50,77,78} whereas isolated administration failed to significantly increase bone formation (Fig. 52.14).⁴⁴ In this way, it is comparable to TGF β that has shown enhancement of bone formation of varying degrees depending on the carrier used,^{80,81} but when combined with PDGF or BMP has resulted in significantly increased bone formation.⁵⁹ VEGF has come into focus as an important cofactor for bone formation for induction of bone tissue in conjunction with BMPs,⁵⁴ due to the abilities

Fig. 52.14 Reconstruction of bone regeneration inside anorganic bovine bone cylinders forming bridging of mandibular defects in minipigs. Incomplete bone fill is visible in scaffolds both with 230 μ g bFGF (a) or without bFGF (b).

both to enhance bone regeneration and increase vascularization.^{55,82}

The only group of growth factors that has consistently promoted bone formation in almost all preclinical settings is the family of BMPs. There are three isoforms of BMPs, BMP-2, BMP-4, and BMP-7 (also called osteogenic protein 1 (OP-1)), that have been explored in the vast majority of studies. Experimental repair of alveolar bone defects, sinus floor augmentations, and mandibular reconstructions has been successfully performed using these molecules.^{83–86} In particular, critical size defect models of the mandible and segmental defects have been evaluated in a number of experimental models with a large variety of carriers. Collagen, collagen/HA/TCP, anorganic bovine bone, hyaluronic acid, PLA/PGA coated gelatin sponges, and PGLA beads have been employed with various doses of either rhBMP-2, rhBMP4, or rhBMP7 in rodents, minipigs, and non-human primates.^{87–93} Another growth factor from the BMP fam-

ily that has been recently introduced into preclinical and clinical testing is growth and differentiation factor 5 (GDF-5). GDF-5, in conjunction with particulate TCP, has been shown to increase bone formation in sinus floor augmentations in minipigs (Fig. 52.15) where it has also proven to be superior to a mixture of the carrier material and autogenous minced bone.^{94,95}

Considering the entire data derived from preclinical testing of growth factors in oral maxillofacial surgery it is very appreciable that the most promising field for the use of growth factors appears to be bone regeneration, in particular the use of BMPs. Nevertheless, data about clinical application of BMPs is still sparse. Recently, BMP2 has received FDA approval for application in maxillofacial reconstruction and a small number of studies in recent years has shown that BMP can be also effective in generating bone in humans.^{96,97} However, not all reports have been clearly convincing for various reasons.^{98,99} One of these reasons is the lack of appropriate delivery

Fig. 52.15 Bone regeneration in sinus floor augmentations with TCP and GDF-5. Significantly enhanced bone volume in sides with GDF-5 (a) compared to sides with the carrier only (b). vehicles for BMP. The carrier that has been approved by the FDA is collagen which has some shortcomings with respect to mechanical strength and release characteristics. Now that the proof of principle has been shown in clinical trials, current research is focused on the mode of delivery in order to make the application of BMPs more effective and reliable.

Delivery vehicles and controlled release

As growth factors are applied to enhance the biological process of tissue regeneration, the tissue-specific levels of cellular communication need to be addressed in an appropriate way. The intensity of the biological signal, i.e. the concentration of the respective growth factor, is supposed to be available at the temporal sequence and the spatial pattern required for the target cells to respond effectively. Unfortunately, neither the temporal sequence of individual growth factor concentrations during tissue repair nor their interaction is close to being clarified. So far, the majority of applications therefore have implanted growth factors that were soaked into various carrier materials with unknown release characteristics with rather arbitrary dosages. Compared to the natural amount of growth factors present during tissue repair, the doses of growth factors applied has always been several orders of magnitude higher. Dosages of growth factors vary also between different animal species. Particularly with respect to BMPs, dosage studies have shown

that moving up the phylogenetic ladder was associated with an increase in dosage required to elicit a biological response. Finally, moving from the preclinical environment into the clinical arena was associated with another huge increase in the amount of BMPs necessary to induce a reliable tissue response.⁵⁷ A recent study about sinus floor augmentations in patients has shown that up to 24 mg/ml of BMP2 per sinus had to be used to produce bone of sufficient quality and quantity to accommodate implants in a second stage operation.⁹⁷ In contrast to this, the native content of BMP in fresh bone tissue is approximately 7 ng/g demineralized bone matrix.¹⁰⁰ The difference between the natural amount of BMPs present at the site of repair and the dosage of BMPs required for clinical use thus is represented by a factor of a magnitude of 10^7 – 10^8 . The need for such excessive doses in clinical therapy has implications with respect to safety and costs on the one hand and has prompted the search for slow-release carriers that could provide a more physiological release profile of the growth factor on the other. As carriers for growth factors also have a mechanical function, in that they should have adequate strength to withstand pressure from overlying or surrounding soft tissue and provide volume for the regenerating tissue, the key question for the clinical application of growth factors is the selection of a carrier that allows for a controlled and retarded release of growth factors and at the same time has the mechanical characteristic required to provide space for tissue regeneration.

Fig. 52.16 Principle of an engineered growth factor (BMP2) that has been modified by a collagen binding site at the N-terminal end of the molecule. (Reproduced with permission from Chen B, Lin H, Wang J, *et al.* Homogenous osteogenesis and bone regeneration by demineralised bone matrix loading with collagen-targeting bone morphogenetic protein-2. *Biomaterials* 2007; 28: 1027–35. Copyright © 2007 Elsevier.)

The majority of delivery vehicles that have been developed and tested in the oral maxillofacial area were used for the application of BMPs. Most of these studies have employed collagen sponges as carriers, on to which BMPs were loaded by soaking the sponge into the growth factor solution. Unfortunately, collagen neither allows for retarded or controlled growth factor delivery nor fulfills the mechanical requirements of a spacemaking device to provide volume for bone regeneration. Delivery studies in collagen carriers have shown that soak loading with BMP is associated with rapid delivery of up to 80% of the growth factor content after implantation within the first 48 hours.^{101,102} As most growth factors carry a heparin-binding domain, binding of heparin to collagen has improved the release characteristic of the collagen carriers towards a more retarded delivery.¹⁰³ Also, addition of a collagen-binding domain to BMP by molecular engineering has significantly improved the efficacy of collagen carriers with respect to bone formation (Fig. 52.16).¹⁰⁴ However, as the mechanical properties still remain insufficient, other carriers have to be taken into consideration.

When delivery vehicles for growth factors are considered, the material characteristics are important for the strategy of growth factor loading and binding to the carrier. Non-resorbable carriers will have to have the growth factor anchored to the material surface, where it can be addressed by approaching cells and/or from where it is released from a chemotactic gradient that attracts target cells and tissue. In contrast, binding of growth factors only to the carrier surface is problematic in resorbable carriers because commencing degradation on the material surface will rapidly release the growth factor together with the superficial layers of the carrier material, leaving behind an entirely passive scaffold that is unable to enhance tissue regeneration during the subsequent period of continued carrier degradation and tissue ingrowth.

Binding of growth factors to the surface of non-resorbable carriers may be considered as biofunctionalization (see earlier in this chapter). Adsorptive loading of biomaterials with growth factors is very dependent on the surface characteristic of the carrier. Physisorption of BMP2 to titanium surfaces has resulted in release of 96–99% of activity within the first hour depending on the surface microstructure.¹⁰⁵ In contrast, adsorption of BMP2 to nanocrystalline diamond-coated titanium surfaces was associated with firm binding of the BMP molecule to the surface with almost no subsequent release.¹⁰⁶ An alternative way of binding growth factors to carriers is the application of linker molecules (chemisorption). Phosphonate anchors that attach to the oxygen of oxide groups on the material surface can be used to bind to the amino groups of growth factor molecules using succinimide chemistry, whereas thiol anchors bind to cysteine residues of organic molecules using maleimide chemistry. The nature of the carrier material and the molecular structure of the growth factor

to be attached frequently determine the choice of linker molecules. Phosphonate anchors are commonly used to couple BMP2 to a carrier surface because the seven cysteine residues are engaged in disulfide bonds within the molecule and in the intermolecular disulfide bond of the dimeric protein.¹⁰⁷ However, both phosphonate and thiol anchors have been shown to significantly enhance the retention of BMPs on the surface of metal, silk, and chitosan compared to untreated controls.^{107–109}

Incorporation of growth factors into resorbable carriers has been explored on several avenues. Soft and flexible delivery vehicles derived from native precursors, such as collagen, silk, or chitosan, have been soak loaded, and coupled to growth factors by covalent binding of heparin groups to collagen,¹⁰³ and by chemisorption using succinimide and maleimide chemistry in silk and chitosan scaffolds.^{106,107} Purely synthetic resorbable carrier materials that have been used as delivery vehicles are PEG and poly- α -hydroxy acids, such as PLA and PGA. PEG is a rather soft and gel-like material that has been successfully tested in conjunction with parathormone and BMP2 but would not fulfill the mechanical requirements to maintain tissue volume and shape in an unprotected defect. PLA and PGA polymers have a much higher stability but are difficult to load with growth factors as they are solid at room and body temperature and would only be amenable to surface coupling of growth factors. If the polymers could be liquefied, growth factors could be mixed with the liquid polymer to provide efficient incorporation. However, the glass transition temperature of these polymers (i.e. the temperature at which the polymers become liquid) is higher than the temperature at which the proteins denature and lose their biological activity. This problem has been addressed by applying organic solvents that are mixed with the polymer granules and the growth factor. After evaporation, a solid implant occurs with the growth factor incorporated into the polymer matrix. This solvent technology has been applied with BMPs¹¹⁰ and has been improved by adding growth factor binding molecules such as heparin¹¹¹ at the preclinical level. However, concerns have been raised in conjunction with this technique about residues of organic solvent that could cause toxic reactions and lead to tissue irritation *in vivo*. An alternative way of incorporating growth factors into the polymer matrix is gas foaming. During this process a lyophilized mixture of polymer granules and growth factor is submitted to high carbon dioxide pressure in a mold. This leads to liquefaction of the polymer at body temperature with homogeneous distribution of the growth factor.^{112,113} During decompression, the liquid polymer transforms into a solid foam that fills the mold. Implants produced with this technology have been successfully tested as slow-release devices for BMP2 *in vitro* and preclinically (Figs 52.17–52.19).^{114–116} As no other agents are added for coupling of the growth factor to the delivery vehi-

cle, the technology may have the potential to produce anatomically shaped degradable implants that are able to release a growth factor in a retarded manner and thereby regenerate tissue in a defined shape. Nevertheless, the promising preclinical results are still awaiting preclinical evaluation in larger animals and clinical testing for use in daily routine.

Cell-based approaches

The strategy of cell-based approaches is to obtain a small number of cells or a small tissue portion through a minimally invasive procedure and to expand these cells *ex vivo* to a volume that can be expected to form the desired amount and type of tissue. In order to produce some 10^8 – 10^9 cells, the initial population of

cells has to be highly proliferative and at the same time inducible into the desired phenotype.

Cell-based approaches are the most complex approaches of all endeavors in tissue engineering because, other than with the application of growth factors, both the host tissue and the biological quality of the seeded scaffolds that are implanted are variable biological success factors. The functionality of these biohybrid constructs depends very much on the survival and the performance of the implanted cells. Thus, besides the local conditions at the recipient site, both the initial cell source and the *in vitro* handling during cultivation of the constructs are important for successful applications.

Cell sources

In vivo, the cell sources for tissue repair are stem cells that are not yet terminally differentiated and have a high proliferative potential. In contrast to embryonic stem cells, which are pluripotent and can differentiate into a large range of different tissues, adult stem cells are already committed to a certain type of tissue such as mesenchymal stem cells. These stem cells can

still differentiate into bone, cartilage, or fat cells, but are limited to tissues of the connective tissue lineage and, thus, are considered to be only multipotent. Several tissues, such as epithelium, bone marrow, liver, and fat tissue have stem cell niches. From these niches the stem cells can be obtained, isolated, and expanded *ex vivo* by *in vitro* technology. Terminal differentiation after sufficient expansion is then induced by conditioning supplements in the culture media.

Research on cell-based approaches is currently focused more or less on the regeneration of bone and cartilage tissue, thus mesenchymal stem cells are of particular interest. Mesenchymal stem cells are commonly obtained from bone marrow aspirates but can also be retrieved from fat tissue. The term mesenchymal stem cell is not quite correct for this type of adult stem cells and has undergone rephrasing several times. Currently, adult stem cells derived from bone marrow are called multipotent mesenchymal stroma cells (MSCs).¹¹⁷ Stem cells derived from fat tissue are referred to as adipose tissue-derived stem cells (ADSCs) and are considered to have very similar properties to bone marrow-derived stroma cells. Stroma cells are isolated as mononuclear cells from bone marrow aspirates by density gradient centrifugation and are separated from hematopoietic stem cells, which are always retrieved simultaneously, by their ability to adhere to the plastic bottom of the culture dishes (Fig. 52.20). Expansion is commonly done by passaging the cells before growth becomes subconfluent and subsequently replating them at low density. Under these conditions MSCs maintain a spindle-shape phenotype and form separate colonies of fibroblastoid cells (Fig. 52.21). The number of these colony-forming units (CFUs) is considered as a measure for the proliferative potential of the cell population. When the expanding cells are passaged at this stage up to 50 population doublings can be achieved without terminal differentiation.¹¹⁸ In mixed cultures, MSCs can be identified by surface markers such as CD106 or STRO1. These surface markers can be used

Fig. 52.20 Bone marrow stroma cells attached to the bottom of the petri dish 4 days after plating.

to further separate MSCs from the population of adherently growing cells by magnetic cell sorting (MACS) (Fig. 52.22) or by fluorescence activated cell sorting (FACS) (Fig. 52.23). After sufficient expansion

Fig. 52.21 Bone marrow stroma cells after 10 days with subconfluent growth of fibroblastoid cells.

sion, osteogenic (ascorbic acid, dexamethasone, glycerophosphate) or chondrogenic supplements (ascorbic acid, dexamethasone, proline, pyruvate) are individually used to induce the respective differentiation of the expanded cells, depending on the tissue that is supposed to be regenerated.

Fat tissue for isolation of ADSCs is commonly derived by liposuction. The technique of tissue harvesting has considerable impact on the viability of retrievable ADSCs. The aspirate undergoes washing and subsequent digestion using collagenase treatment. After centrifugation and resuspension of the resulting pellets, the cells are plated at low density of (100 cells/cm²). CFUs resulting from this procedure can be expected to range between 0.1 and 5% of the retrieved nucleated cells.¹¹⁹

Epithelial stem cells are more difficult to isolate and expand. Gingiva epithelial cell isolates have been derived from trypsin digestion of gingival tissue and stem cell clones identified by size gated FACS after immunolabeling against $\beta 1$ integrin¹²⁰ or by MACS using antibodies against neurotrophin receptor p75.¹²¹ Clones with high colony-forming efficiency (CFE) are retrieved by these measures that are able to produce up to 30 population doublings.¹²⁰

Cell-based approaches have been tested *in vivo* in a large number of preclinical studies. In oral and maxillofacial surgery they focus on the regeneration

of bone, cartilage, and epithelial tissue. In bone tissue engineering, cell-seeded scaffolds have been evaluated using autogenous cells in various animal models and using human cells in a xenogenic model in immunocompromized rodents. While the autogenous models have almost consistently shown an enhancing effect on bone formation when compared with non-seeded scaffolds,^{122–127} xenogenic models using human cells have produced ambiguous results in that some reports have been unable to show that bone formation in scaffolds seeded with native bone marrow stroma cells has been superior to control scaffolds undergoing osteoconductive bone ingrowth.^{128–131}

Cartilage tissue engineering in oral and maxillofacial surgery is limited very much to the temporomandibular joint (TMJ). Some recent reports have dealt with tissue engineering of nasal cartilage^{132,133} but most of the current work is directed towards replacement of the TMJ disc and condylar cartilage.^{134–136} One of the major problems to overcome in tissue engineering of TMJ cartilage is the specific structural requirements of tissue engineered TMJ cartilage to withstand the *in vivo* forces as well as the fixation and connection of remaining ligaments. The mechanical properties of this type of cartilage have to enable the tissue not only to take pressure but also a high level of tension.¹³⁶ Thus, the characteristics of common hyaline cartilage that is used by many tissue engi-

Fig. 52.23 Plot from a FACS analysis showing separation of multifunctional stroma cells according to their surface markers.

neering approaches to replace joint cartilage will not be appropriate to replace TMJ cartilage.¹³⁴

Engineering of epithelial tissue has moved from the use of epithelial monolayer sheets in the 1980s^{137,138} to more complex constructs that contain a stratified epithelium, a continuous basement membrane, and a fibrous connective tissue layer that supports the epithelium and gives three-dimensional stability during handling and healing. These engineered full-thickness oral mucosa constructs are commonly referred to as *ex vivo* produced oral mucosa equivalent (EVPOME).¹³⁹

Clinical applications of cell-based approaches in oral and maxillofacial surgery have been limited to the repair of bone tissue and epithelial defects. In bone tissue engineering, periosteal cells from the mandibular ramus and bone-derived cells from the maxillary tuberosity have been used to produce bone in sinus lift procedures and lateral rim augmentations in preimplant surgery.^{140,141} However, only 18 of 27 sinus lifts with periosteal cells seeded in polymer fleeces resulted in sufficient bone formation for secondary implant placement.¹⁴⁰ Moreover, resorption of tissue-engineered bone from periosteal cells in polymer fleeces was significantly higher than after sinus lifts using autogenous bone.¹⁴² In contrast, bone marrow stroma cells suspended in a fibrin matrix containing PRP as "injectable bone" without defined three-dimensional scaffold have been successfully used to enhance bone formation in alveolar bone distractions and in sinus floor augmentations.^{143,144} The fact that all patients in whom PRP and cells were used had been successfully treated compared to only 18 of 27 patients treated with polyglycolic scaffolds and cells alone suggests that the presence of growth factors may enhance the functionality of cell-based approaches, in that proliferation and vascularization of the seeded cells is enhanced after implantation in the *in vivo* environment. Cell-based approaches in combination with growth factors – in particular BMPs – have been used for flap prefabrication in major reconstructive procedures by implantation into the latissimus dorsi muscle and subsequent revascularized transfer to a segmental defect of the mandible (Fig. 52.24).¹⁴⁵ These procedures may not be cost

Fig. 52.24 Reconstruction of the mandible with a precultivated piece of bone in a titanium cage. (Reproduced with permission from Warncke PH, Springer IN, Wiltfang J, *et al.* Growth and transplantation of a custom vascularized bone graft in a man. *Lancet* 2004; 364: 766–70. Copyright © 2004 Elsevier.)

effective yet when compared to the established methods of revascularized tissue transfer for mandibular reconstruction, but they add to the knowledge of tissue engineering and may help to gather experience of how the principles of tissue engineering can be accommodated in the current strategies of maxillofacial reconstruction.

Clinical tissue engineering of epithelium using EVPOME (Fig. 52.25) preparations has been employed in intraoral applications such as vestibuloplasty, repair of superficial postablative mucosal defects, and for prelamination of free radial forearm flaps with subsequent transfer to the oral cavity.^{146–148} Clinical results have shown a good to excellent take rate with vascular ingrowth from the recipient bed with the total wound healing time being shorter than in the control defects covered with unseeded scaffolds only.^{118,148,149}

Recombinant cells

One of the weaknesses of cell-based approaches is the fact that the implanted cells have to rely on the host tissue to provide the biological signals and environmental factors that are necessary to revascularize the implanted constructs as rapidly as possible and at the same time maintain the biological quality of the implanted cells inside the scaffolds. This has prompted the idea to use gene transfer to the seeded cells that would allow for overexpression of the required growth factors which make them less dependent from the level of host tissue factors. Thus, the functionality of the implanted devices could be increased and the therapeutic outcome improved.

Gene transfer requires complex delivery strategies because extracellular DNA is not readily incorporated and not easily put into function in the target cells. The gene that is supposed to be transferred has to be incorporated into a so-called vector and this vector has to pass through the cell membrane. The most

Fig. 52.25 EVPOME showing stratified epithelium on the surface after 11 days in culture. (Reproduced with permission from Izumi K, Feinberg SE, Ida A, Yoshizawa M. Intraoral grafting of an *ex vivo* produced oral mucosa equivalent: a preliminary report. *Int J Oral Maxillofac Surg* 2003; 32: 188–97. Copyright © 2003 Elsevier.)

frequently used delivery vehicles for genes are plasmids – small circular molecules of DNA. The DNA that encodes for the protein of interest is cloned into the plasmid. This plasmid commonly also contains a promoter area that activates the gene and an additional reporter gene such as green fluorescent protein (GFP) or β -galactosidase. These reporter genes encode for proteins that allow for following the plasmid after delivery (Fig. 52.26).

The introduction of plasmids into the cells is one of the main hurdles during gene transfer. The strategies for incorporation can be divided into non-viral delivery and viral-mediated transfer. Non-viral delivery is accomplished using chemical supplements such as calcium phosphate complexes that facilitate passage through the cell membrane. Alternatively, lipofection has been employed which uses liposomes that encase the plasmid vectors to pass through the cell membrane. Liposomes bind to the cell membrane and are incorporated through endocytosis. After intracellular digestion of the vesicle membrane the vector is delivered. Non-viral gene transfer has the advantage of being rather inexpensive, less complex and safer with respect to biological hazards than viral gene delivery strategies. However, transfection efficacy has been reported to be rather poor due to a low degree of integration of the transferred gene and – if successful integration has been accomplished – a rather short transient gene expression period.

Fig. 52.26 Fluorescence microscopic image of rat calvarial defect edges showing cells positive for green fluorescent protein (GFP) after injection of medium containing adenoviral vectors containing the BMP2 gene and the reporter gene for GFP into the defect (a) compared to negative signals after injection of medium only (b).

Viral gene transfer uses replication-defective virus particles to manage the cell membrane passage and the functionalization of the transferred gene. After removal of pathogenic gene sequences from these virus particles, their ability to deliver genetic material to host cells is used to transfect the target cells with the respective gene. A wide range of viral vectors is available, including adenoviruses (AVs), adeno-associated viruses (AAVs), and retroviruses such as lentiviruses (LVs). While adenoviral vectors remain in the cytoplasm of the target cells, retroviral vectors integrate their DNA permanently into the genome. In this way, viral gene transfer using retroviral vectors is more effective than using adenoviral vectors. However, concerns have been raised that random integration of the transferred gene into the genome of the target cells might activate oncogenes and increase the biological hazard of this approach.

The use of gene transfer in tissue engineered devices in oral and maxillofacial surgery has been performed so far only in a few approaches at the pre-clinical level. Experimental studies have used genetically modified human marrow-derived stroma cells¹²⁹ and mesenchymal stem cells¹⁵⁰ overexpressing BMPs. In these studies, the transfected cells produced significantly increased amounts of bone compared to the native cells and the reporter gene-transfected cells in both ectopic¹⁵⁰ and orthotopic sites.¹²⁹

In TMJ cartilage tissue engineering, successful attempts have been made to engineer an osteochondral condylar implant in ectopic sites in rodent models using biphasic scaffolds, transduced fibroblasts (BMP-7), and chondrocytes.¹⁵¹ Also, adenovirally stimulated (AdBMP-2) mesenchymal cells from periosteum and bone marrow have been used successfully to repair TMJ cartilage defects.¹⁵²

Epithelial cells have been transduced using lentivirally mediated gene transfer¹⁵³ and particle bombardment (gene gun), not for tissue engineering purposes, however, but as a therapeutic *in situ* approach for diseased skin and neoplasms.

In vitro technology

The successful *ex vivo* production of a tissue equivalent is not only based on the isolation and expansion of the respective populations of cells with specific properties but also on the appropriate *in vitro* technology to arrange and distribute these cells inside the three-dimensional scaffolds. Moreover, nutrient supply and removal of metabolic end products have to be provided during extended periods of cultivation. The use of *in vitro* technology is based on the specific requirements of the type of tissue equivalent that is intended to be produced. The production of mucosa equivalents, for example, requires simultaneous cultivation of epithelial cells and gingival fibroblasts in thin scaffolds and conditions of cultivation have to allow for the occurrence of a stratified epithelial layer on the surface. On the other hand, the thin constructs

do not depend on an active media exchange within the scaffold as they can rely on diffusion for metabolic exchange. Cultivation of EVPOME is, therefore, performed on permeable membranes floating at an air/liquid interface for a period of 7 days after they have formed a continuous epithelial monolayer on the scaffold during submerged cultivation for 4 days.¹⁴⁸ In this way, multilayered constructs can be produced that quite closely resemble native mucosa in terms of morphological, histochemical, and genetic patterns.^{154,155}

Production of seeded scaffolds for bone tissue engineering is different as it is commonly performed in large volume scaffolds that are seeded with only one type of specialized cells. Currently, a uniform

distribution of these bone-forming cells inside the scaffolds is considered to be advantageous for *in vivo* osteogenesis.¹⁵⁶ Technical support is required, therefore, to achieve complete seeding of the whole scaffold volume and also to provide continuous exchange of culture media in the center of the seeded devices when long-term cultivation is intended to produce a mature tissue equivalent.

In general, the strategies for seeding and cultivation of cells in scaffolds can be divided into static and dynamic approaches. Conventional static seeding of biomaterials with cells has been performed by droplet seeding followed by static culturing with media exchange in intervals of 2–7 days. However, in bone tissue engineering, droplet seeding of mesenchymal cells has been shown to result in non-homogeneous distribution of cells inside the scaffolds (Figs 52.27 and 52.28);¹⁵⁷ subsequent static cultivation had to rely on diffusion for the exchange of culture media in the central portions of the scaffolds, which resulted in apoptosis of cells in these scaffold areas. In order to improve the distribution and the viability of seeded cells across the entire scaffold volume, technologic approaches for dynamic cell seeding and culturing were developed. Low pressure or vacuum have been employed during seeding to improve cell penetration into the scaffolds and increase cell density in the central parts of the scaffold.^{158,159}

Dynamic culturing has been developed in many ways and individual applications have been used to satisfy the requirements of the specialized cells of the various tissues or organ composites to be produced. Traditional methods of agitated cultures using rotary vessels or spinner flasks^{160,161} are being replaced by perfusion bioreactor systems, which produce a constant medium flow through the scaffolds, that provides continuous nutrient supply and removal of

Fig. 52.27 Distribution of MSCs seeded on to a porous CaCO_3 scaffold with non-homogeneous distribution of the cells in a cross-section through the scaffold. Cell nuclei are stained blue.

Fig. 52.28 Numerical evaluation of cells in a CaCO_3 scaffold. Note concentration of cells at the edges of the block with a relatively void center.

metabolic end products (Fig. 52.29).¹⁶² Recent developments include micromechanical manipulations in advanced reactor models.^{163,164} Dynamic seeding and culturing of human mesenchymal stem cells in perfusion bioreactor systems has produced more uniformly distributed cells and ECM proteins than static culturing.^{165,166} Dynamic culturing in spinner flasks has been reported to enhance the activity of alkaline phosphatase as a marker of bone-specific activity and other markers of osteogenic differentiation^{167–169} compared to static conditions. Culturing of bone marrow stromal cells in flow perfusion bioreactors has improved mineralized matrix deposition by increasing fluid shear forces^{167,168} and increased the content of VEGF.¹⁶⁹ Too high flow volume, however, can also be detrimental for cell survival and differentiation.¹⁷⁰

Beyond the beneficial effect of dynamic seeding and culturing on cell functions *in vitro*, the efficacy of these techniques with respect to *in vivo* bone formation has not been clearly proven yet. Experimental studies on static vs dynamic culturing of small volume scaffolds with human trabecular bone cells have shown that static vs dynamic culturing conditions did not affect the degree of bone formation,¹⁷¹ whereas dynamic seeding of rat bone marrow stroma cells produced more bone *in vivo* than static culturing.¹⁵⁸ The positive effect of dynamic culturing on cell survival inside large-volume scaffolds has been recently shown *in vitro*.¹⁷² Preclinical studies using this type of advanced *in vitro* technology now have to show that cell survival and graft function are also improved *in vivo*.

Future perspectives

A number of basic questions about the application of tissue engineering in clinical therapy are still unanswered. For cell-based approaches these questions

relate to the simulation of tissue-like conditions with respect to scaffold nature, biological signaling for cell/tissue development during *ex vivo* cultivation, and nutrition and cell survival after implantation into the *in vivo* environment. Major leaps in *in vitro* technology will be required to construct a tissue-like structure that has the quality of an autogenous graft, which is still the gold standard. Moreover, in situations that require revascularized tissue transfer, it is even more difficult to imagine the construction of a tissue-engineered scaffold that is equivalent to the composite flaps of today's standard, including vessels, bone, and soft tissue. Looking back, the vision of getting cells and scaffolds together to form a tissue may have been too simplistic. Future efforts in the clinical application of cell-based approaches in oral and maxillofacial reconstruction will have to be more complex by combining more than cells and scaffolds and trying to create active scaffolds that resemble the function of ECM more closely. By designing engineered microenvironments that bring physical regulatory factors into play, novel approaches can be developed that provide adequate interactive stimuli for organic tissue development. Research in biomaterials that allow for cell attachment and growth, and at the same time can store and release biological signals at a physiological level, may help to form constructs that take part in the natural remodeling activity during regeneration and support survival and function of the seeded cells. In this way, the quality of autogenous grafts could be improved.

The complexity of problems with the use of cells has resulted in the fact that the application of cell-based approaches is currently less advanced in clinical tissue engineered reconstruction than the use of growth factors. Recombinant growth factors will probably have the widest clinical application in bone reconstruction in the immediate future. Their effective use in terms of costs and safety will be linked to

Fig. 52.29 Schematic drawing of a bioreactor.

the development of appropriate delivery vehicles. Additionally, the simultaneous use of multiple growth factors that act synergistically and over-additively in tissue regeneration will help to lower the amount of individual growth factors to be released. Future research will have to elucidate this network of interactions and simulate their interplay with the help of controlled-release carriers.

"Still, to date tissue engineering has not lived up to its promise. In a very real sense, it has underdelivered, although the potential is still there."¹⁷³ This statement makes clear that from the clinical perspective not many of the numerous promises that were anticipated in the early years of tissue engineering have yet become reality in our daily routine. However, with ongoing research the growing body of knowledge creates a much better understanding of tissue repair and how tissue function can be enhanced or supported. Nevertheless, all researchers and clinicians involved in this process are aware that this will be a slow-growing evolutionary process rather than a revolutionary breakthrough.

Chapter 53

Cosmetic Facial Surgery

Joe Niamtu

The chapter is a comprehensive overview of different cosmetic surgical procedures in the maxillofacial region to enhance the soft tissue esthetics. Minimally invasive techniques as well as more demanding cosmetic surgical procedures are described and illustrated. The author claims that over the last four decades dentistry has been transformed from a specialty primarily treating disease to a specialty with focus on esthetics and reconstruction.

Blepharoplasty procedure, 1159
Postoperative care, 1169

The expansion of this topic in oral and maxillofacial surgery has been exponential. It would probably not have been appropriate to include this topic in an oral and maxillofacial surgery text 15 years ago, but much has changed in this specialty in a decade. To appreciate this change we must understand the changes that have occurred in dentistry. Over the past four decades dentistry has transformed from a specialty that primarily treated disease (dental caries) to a specialty with the main focus of esthetics and reconstruction. Orthodontics, periodontal plastic surgery, cosmetic dentistry, and implantology all share the common focus of esthetics.

Oral and maxillofacial surgery has also progressed and includes cosmetic facial surgery in its contemporary scope.¹ In the USA cosmetic facial surgery represents core curriculum in most oral and maxillofacial surgery programs, is part of the board exams, and is covered by oral and maxillofacial surgeons' malpractice insurance.

Although the progression has been rapid, it has been hard fought with competing specialties.² Despite

this opposition, oral and maxillofacial surgeons have won the privilege to perform cosmetic surgery in virtually every state in the USA in which it was contested by competing specialties. With this successful legislation and the contemporary training, many oral and maxillofacial surgeons have included cosmetic facial surgery in their practices.

Most oral and maxillofacial surgeons will not choose to limit their practices, and this chapter is designed as an overview of contemporary and common techniques. Due to the limited scope of this chapter it is impossible to cover all cosmetic procedures in great detail. The main goal of writing this chapter is to provide a brief overview of common cosmetic facial procedures to elucidate the basic techniques and provide advice on avoiding complications. The descriptions are time tested in the author's practice and have produced a low complication rate and happy patients. These descriptions are subject to the individual surgeon and obviously vary greatly from surgeon to surgeon. There are many ways to approach any procedure and each practitioner must decide personally what works best.

Minimally invasive cosmetic facial surgery procedures

As technology has progressed, minimally invasive cosmetic procedures have surpassed surgical procedures on an international basis. Botox and injectable fillers represent the most commonly requested cosmetic procedures.

Botox (botulinum toxin A)

The application of Botox in cosmetic facial surgery represented a true paradigm shift where significant effacement of facial lines and wrinkles could be treated non-surgically. Botox causes temporary paralysis of skeletal muscle by preventing the release of acetylcholine at the motor end plate.² This effect will persist about 90 days in the average patient.

There are multiple botulinum toxin preparations worldwide, and differences exist in dilution and units given; this chapter will only describe Botox Cosmetic as marketed in the USA. A Botox vial contains 100 units of toxin and can be diluted with various amounts of saline. The author dilutes each vial with 5 ml of preserved saline. This amount makes five syringes that contain 20 units each, which is the average amount used for a single treatment area.³ It is important to keep in mind that it is the number of units delivered and not the actual dilution that is critical.

The most common areas treated are the frown lines (brow depressors), horizontal forehead lines (frontalis), and crow's feet (lateral orbicularis oculi). The single biggest tip to heed when injecting Botox is to not inject closer than 1 cm to the orbital rim. This provides a safety margin to prevent the toxin from diffusing into musculature that it is undesirable to affect.

Treating the brow depressors

The author uses a Leur-Lock 1 ml tuberculin syringe with a 32 gauge needle for all injections. To treat scowl lines a total of 20 units is injected for the average patient: 5 units are injected into the procerus area,

Fig. 53.1 Five injections across the brow depressors (a total of 20–25 units) adequately treat the “frown lines” in most patients.

Fig. 53.2 Multiple injections for an average of 20–25 units will adequately prevent the horizontal forehead wrinkles when flexing the frontalis muscles.

4 units are injected into each corrugator supercili area, and 3 units are injected into each lateral orbicularis oculi area (Fig. 53.1).

The frontalis is treated by injecting 2–3 units across the areas of the forehead that wrinkle with animation (Fig. 53.2). Since Botox will diffuse 10–15 mm circumferentially, the goal is to treat the entire forehead by spacing the injections. It is advisable to reduce the treated area above the lateral brow in patients with redundant eyelid skin (dermatochalasis). Failure to do so can accentuate the droopy lid skin because the frontalis deactivation prevents the patient from being able to lift the brow. In these patients it is better to taper out the treated areas so the area above the lateral brow is very lightly treated. If the patient desires less movement, more Botox can be injected at a later date. Men (having more muscle mass) or women with high hairlines may require more than 20 units for successful treatment.

Crow's feet wrinkles are treated by injecting 3 units of Botox into the lateral orbicularis oculi in three areas in a semi-lunar fashion (Fig. 53.3). It is important to avoid the superficial vessels in this area to prevent bruising.

Perioral Botox

Using Botox around the mouth is very different to its use in the upper face and the results are much less dramatic. In addition, overtreatment of the orbicularis oris musculature can cause significant dysfunction. The primary use of perioral Botox is to reduce vertical rhytids: 1–2 units of Botox are injected very superficially (almost intradermally) in the area across the upper and/or lower lip (Fig. 53.4). The patient is first asked to pucker to show the wrinkles that need injection. Since this area is so sensitive to overtreatment, it is advisable only to inject a single unit in each area, then have the patient return for reinjection a week later. The author most commonly injects this area in conjunction with filler treatment.

Fig. 53.3 Three injections of 3 units each in the lateral canthal region will improve “crow's feet” wrinkles in the average patient.

Fig. 53.4 Improvement of the upper and lower lip rhytids after 8 units in each lip performed in two sessions of 4 units across each lip.

Fig. 53.5 5–15 units of toxin are injected in the most evident palpable muscle mass during clenching. This is repeated every 2 weeks until the result is achieved.

Botox for masseteric hypertrophy

Botox injection is commonly used for esthetic and functional treatment of the masseter muscles. The treatment involves injecting the muscle mass until the size and/or bite force are decreased. Prior to injection, the patient is asked to clench their teeth, then the surgeon palpates and injects the most prominent areas of palpable and visible mass. Usually 5–10 units are injected in several areas on each side, then the patient returns 2 weeks later for reinjection if necessary (Fig. 53.5). This is continued over several sessions until the desired end point. A 32 gauge, 13mm needle is used, burying the entire length for deep injections.

Figs 53.6–53.10 show typical before and after Botox treatments.

Fig. 53.6 A patient before and 1 week after Botox injections to the brow depressors to improve the frown lines.

Fig. 53.7 This patient is shown elevating her brows before and 2 weeks after 20 units of Botox across the frontalis muscles.

Fig. 53.8 This male patient is shown before and 2 weeks after 12 units of Botox in each lateral canthal region.

Fig. 53.9 This patient is shown before and 1 month after multiple injections of Botox into each masseter. The patient is clenching in both pictures.

Fig. 53.10 This female patient is shown before and 1 month after two injection sessions of 4 units across each lip. The total of 8 units in each lip has reduced the severity of the wrinkles.

Injectable facial fillers

Differences exist in the availability of fillers in various countries. Europe, Canada, and Australia have pioneered fillers that have only recently become available in the USA, and currently use others that are not yet available in the USA. A decade ago, bovine-based collagen fillers were the principle fillers in use, but there are now many more options of injectable materials. The scope of this chapter prohibits in-depth description of each filler. Every filler has specific advantages and disadvantages. It is important to understand the material composition of each filler, its longevity, and most importantly the proper tissue plane for injection. The latter is perhaps the most critical factor as different fillers are intended for superficial dermal injection, mid to deep dermal injection, and subdermal injection.

Filler technique for nasolabial folds

Cutaneous injection can usually be performed with topical anesthesia only, although some patients may require supplemental local infiltration.⁴ Patients may think that the filler will make their folds disappear so it is important that they understand that the filler will blunt the folds and make them less noticeable, but it won't eliminate them.

Since many tissue planes come together at the nasolabial fold, injected filler sometimes has a tendency to flow laterally; if this occurs it can actually make the fold larger. If the surgeon notices lateral flow it is important to withdraw the needle and continue medial to the fold.

Correct tissue placement of most fillers is in the mid to deep dermis. When the filler is in the correct plane the wrinkle or fold should visibly improve as the filler is injected. Failure to see immediate correction may mean that the needle is too deep and the filler is spreading laterally in the subcutaneous plane instead of filling the dermis. Filling techniques include serial puncture, which involves multiple sticks with filler deposition along the fold or wrinkle, or linear

Fig. 53.11 Linear threading and serial puncture techniques are common methods used in filling facial lines, wrinkles, and folds.

threading, which involves a single puncture, threading the filler as a line while withdrawing the needle.⁵ Fig. 53.11 shows the described filling techniques and Fig. 53.12 shows a before and after picture of nasolabial filling. Individual skin wrinkles are treated basically the same way, but usually more superficially in the dermis.

Massaging any injected area (wrinkle or lip) helps coalesce the injected filler and thereby reduces the lumpy feeling or appearance. All but the youngest patients usually require a syringe for each fold. One problem that exists is that for financial reasons many patients will only want to pay for a single syringe split between both folds. Failing to use the proper amount of filler will result in a subclinical result and an unhappy patient.

Filling the lips

This section will provide a basic discussion on filling the lips. The main concerns of lip rejuvenation are restoration of definition and volume, and improvement of vertical rhytids (lipstick lines). Obviously, other applications exist, such as perioral filling, and filling the commissures and mentolabial folds, but these are beyond the scope of this chapter.

The youthful lip has pleasing definition with an angular Cupid's Bow, a plump white roll, and defined philtral columns. The aging lip loses this definition and becomes flat and devoid of definition.⁶ Every patient is different when it comes to lip rejuvenation. Younger patients may only require slight plumping, whereas older patients may need plumping, Cupid's bow enhancement, and vertical rhytid filling.

Defining the vermillion/cutaneous junction

The youthful upper lip has a well defined Cupid's bow area with the shape of a lazy "m" configuration and the lower lip has more of a curvilinear vermillion/cutaneous junction. The upper lip constitutes one third of the total lip volume and the lower lip has the ideal proportion of two thirds of the total lip volume (Fig. 53.13).

To reproduce the white roll the filler needs to be injected into the potential space that exists between the lip mucosa and orbicularis muscle. It takes some experience to appreciate this tissue plane. When the needle is in the proper submucosal potential space,

Fig. 53.12 This patient is shown before and after 1ml of Jevoderm injected intradermally into each nasolabial fold.

the filler will flow antegrade and retrograde with little syringe plunger pressure. If increased plunger pressure is required or if the filler creates a lump instead of flowing freely, the needle is in the incorrect plane (Fig. 53.14).

The filler should be injected conservatively in the center of the lip to create the “v” inferior to the philtrum. Next, the lateral limbs of the upper lip white roll are augmented. The filling of this area does not usually require filling all the way to the commissure areas. Most females look best with only the central third of the lip (the “pucker” area) augmented. The curvilinear white roll of the lower lip is likewise filled in the same manner (Fig. 53.15).

Creating pout: restoring lip volume

Simple volume is created in the lips by injecting “pillows” of filler deeper in the lip (Fig. 53.15). The target for volume filling is to inject the filler one third to one half the thickness of each lip. This is done at the level of the wet/dry line. For the average patient a single syringe will sufficiently fill and outline both lips, but some patients will require additional product.

Treating vertical lip rhytids

Some patients present with the desire to fill lipstick lines but do not desire bigger lips. The individual lines can be filled but the surgeon must be careful not to create a series of “speed bumps” across the lips. When filling solitary lines a less viscous filler such as Cosmoderm or Juvederm (Allergan Inc, Irvine, CA)

Fig. 53.13 The esthetic upper lip is about one third of the lip volume while the lower lip represents about two thirds of the total volume.

Fig. 53.14 (a) The correct needle position for filler injection in the potential space under the lip mucosa. Injection in this plane should be free flowing with minor syringe pressure. (b) “Lumping” of the injected filler in the incorrect plane. Increased syringe pressure without free filler flow signals incorrect placement.

may be used. These less viscous fillers can be injected with great accuracy and can fill isolated rhytids without gross lip volume. By employing the white roll definition technique mentioned earlier, the lipstick lines are often simultaneously improved from the subtle stretching of the lip skin.

Figs 53.16–53.19 show before and after pictures of lip enhancement techniques.

Cervicofacial liposuction

Liposuction is not a procedure to reverse obesity but rather to deal with isolated fat deposits of the neck and face. The submental, jowl, and lateral neck regions are the areas most commonly treated. Patient selection is critical for successful outcomes. Younger patients with isolated submental fat and tight neck skin are the best candidates. Patients with skin laxity

Fig. 53.15 The areas of filler injection used in the lips. Outline of the white roll, philtral column bases are illustrated as thin lines whereas the deeper fill for pout is shown as larger depositions.

Fig. 53.16 This patient was treated with one syringe of Cosmoplast in each lip.

Fig. 53.17 This patient was treated with a single syringe of Restylane split between both lips.

Fig. 53.18 This patient was treated with a single syringe of Juvederm Ultra split between both lips.

Fig. 53.19 The pictured patient was treated with 1.6 ml (two syringes) of Juvederm Ultra Plus.

of the neck must be approached with caution as the redundant skin may become more pronounced after fat removal. Although liposuction can induce skin tightening, it is much less dramatic in older patients. Patients that exhibit significant neck skin excess are candidates for facelift surgery. Another caveat of liposuction is overly aggressive removal of fat. Fat is often viewed as a cosmetic enemy but oversuctioning the neck will cause extremely unattractive and difficult to correct changes in the anterior neck. Removing too much subcutaneous fat or not leaving an adequate fat cushion on the dermis can cause the skin to tether down on the platysma muscle, producing a webbed deformity. The author prefers to stay on the subcutaneous plane when performing neck liposuction. Some surgeons advocate removal of subplatysmal fat and it can, at times, be beneficial but can also result in a submental concavity known as a “cobra” deformity. Removal of subplatysma fat should be reserved for experienced surgeons.

Procedure

The procedure can be performed with local anesthesia only or with supplemental intravenous sedation. The patient is marked in an upright position with a surgical marker to outline the fat deposits in the anterior neck and jowls as well as the inferior border of

Fig. 53.20 The subcutaneous fat deposits in the superficial jowl and submental region are characterized in this diagram.

Fig. 53.21 Tumescent local anesthesia is injected in the subcutaneous plane. This provides anesthesia, hemostasis, and hydrodissection. After waiting 10–15 minutes, the fat is suctioned.

the mandible and the submental crease. Fig. 53.20 shows the usual fat deposits and surgical markings for cervicofacial liposuction.

Tumescent anesthesia is mixed to a concentration of 1% lidocaine and 1:1 million epinephrine. This can be made up by adding 1 ampoule of 1:1000 epinephrine and 50 ml of 2% lidocaine to 1 liter of normal saline. The solution is injected in the subcutaneous plane around all areas to be treated. Generally 40–100 ml are injected in the submental area and about 20–30 ml in the jowl area (Fig. 53.21). The solu-

Fig. 53.22 The common cannulas used in facial liposuction and the approximate borders of the submental fat deposits.

Fig. 53.23 Jowl fat being suctioned from an earlobe incision. This is a safe surgical area in the subcutaneous plane.

tion is injected until the tissue turgor is “as hard as wood” and the operator needs to wait a sufficient time until the tissues are well blanched before beginning.

A stab incision is made in the submental crease with a number 15 scalpel blade to the subcutaneous plane and the liposuction cannula is inserted. The author prefers to begin with a 1 mm multiport cannula and progress to larger sizes, and uses simple wall suction for the face. The actual liposuction process involves a rapid and reciprocating in and out movement of the cannula. The process should also involve a criss-cross technique where the areas are suctioned from multiple vectors to increase the efficiency of fat removal. The area traditionally suctioned is from the mandibular border to the thyroid cartilage, between the medial borders of the sternocleidomastoid muscle (Fig. 53.22). This area is quite safe if the surgeon stays in the subcutaneous plane. The incision is then closed with several 5/0 gut sutures.

The safest means of approaching the jowl fat deposits is from an earlobe incision. A stab incision is made at the junction of the inferior lobe and cheek skin. The cannula is inserted in the subcutaneous plane to the jowl area to be treated (Fig. 53.23). This area must not be overtreated and patient expectations must be minor to moderate. Figs 53.24 and 53.25 show patients treated with liposuction only. The author frequently performs chin implant surgery on liposuction patients, which can greatly enhance the profile result (Fig. 53.26).

Midface implants

The midfacial area is perhaps the most overlooked area of facial rejuvenation. As we age, the midface becomes ptotic and gaunt and what was the cheeks becomes jowls.⁷ Although there are numerous ways to rejuvenate the midface, facial implants carry

numerous advantages. They come in many anatomic shapes and sizes, are a permanent solution, are reversible, are easily placed and removed, and look and feel natural. In general, most patients require

Fig. 53.24 This patient was treated with submental and jowl liposuction only.

Fig. 53.25 This patient was treated with submental and jowl liposuction only.

Fig. 53.26 This patient was treated with submental and jowl liposuction in addition to a silicone chin implant.

Fig. 53.28 The subperiosteal dissection for cheek implants includes the anterior maxilla and crosses the malar region to taper off over the zygomatic arch.

augmentation in one of three areas or a combination of these areas. For the patient that wants more of a zygomatic, “high cheekbone” look the malar shell implant is considered. For those patients requiring a more maxillary augmentation the submalar type implant is recommended. When patients would benefit from both malar and submalar augmentation, the combined submalar implant is used (Fig. 53.27).

Cheek implant technique

Cheek implants can be placed with local anesthesia and/or intravenous sedation. They are always placed in the subperiosteal plane, although it is common for the lateral portion of the implant to lie over the masseteric tendon. Local anesthesia is infiltrated over the anterior and lateral maxilla and over the medial zygomatic region from a transcutaneous approach. Intraorally, several milliliters of local anesthetic are also infiltrated in the mucosa above the canine tooth. An incision is made in the sulcular region above the canine tooth to the subperiosteal plane. Using a periosteal elevator, dissection is performed over the anterior maxilla and the malar region with the dissection tapering off over the zygomatic arch (Fig. 53.28). Care is taken to avoid and protect the infraorbital nerve. The dissection should taper off as it reaches the zygomatic arch.

Fig. 53.27 The common implants used by the author include (a) the submalar implant for anterior maxillary fill, (b) the malar shell implant (for “high cheekbones”), and (c) the combined submalar implant for augmentation of the anterior maxillary area as well as the malar area.

The larger implants require inferolateral dissection to accommodate the implant. It is not uncommon to require dissection over the origin of the masseteric tendon at the lateral malar region, and it is not a problem for a portion of the implant to cover this area. The dissection pocket need only be slightly larger than the actual implant. Making the pocket too large increases mobility. Although chin implants should always be fixated, this is rarely done with cheek implants as experience has shown that it does not affect the result. After dissection, the pocket is irrigated with an antibiotic solution and the implant placed in the pocket (Fig. 53.29). It is critical to make sure the implant lies passively and the tail is not folded or bent. The incision is closed with 4/0 gut suture. The patient is asked to refrain from significant oral function for several days and is warned that smiling, puckering, or speaking may be slightly impeded for 1–2 weeks. Figs 53.30–53.32 show before and after pictures of patients with midface implants.

Cosmetic blepharoplasty

The periorbital tissues frequently show signs of aging earlier in life than does the lower face. Eyelid aging

Fig. 53.29 The implant pocket should be only large enough to accommodate the implant which is placed through the intraoral incision. Too large a pocket can cause implant mobility.

Fig. 53.30 This patient underwent facelift, laser skin resurfacing, and placement of a medium submalar silicone cheek implant.

changes are manifested by pseudoherniation of periorbital fat, loose and wrinkled lid skin, lateral hooding, and brow ptosis.⁸ If brow ptosis is significant, it should be addressed with a brow lift. The generalized goal of blepharoplasty is to reduce excess skin and fat and sculpt the eyelid by redefining the youthful lid crease.

It is extremely important to have a firm understanding of the anatomy of the periorbital area as well as the basic tenets of blepharoplasty surgery. Due to the fact that people only have two eyes and vision is a most precious sense, utmost care must be exercised in cosmetic blepharoplasty which is an elective procedure. The goal of cosmetic blepharoplasty is to reduce the excess skin, muscle, and fat, and to produce a sculpted eyelid complex that replicates that of youth. This is a surgical procedure where it is mandatory to be conservative as it is not hard to produce irreversible changes that can lead to corneal damage, visual problems, and, in extreme cases, blindness.

Evaluation of the blepharoplasty patient

As we age, the eyelid skin becomes redundant, crepe like, and sun damaged. These skin changes of the eyelid skin are known as dermatochalasis. In addition,

Fig. 53.31 This patient underwent placement of medium combined submalar shell silicone cheek implants.

Fig. 53.32 This patient underwent placement of medium submalar silicone cheek implants with a mini-facelift.

tion, the forehead and brow complex undergo ptotic changes which contribute to the lateral eyelid ptosis known as hooding. Finally, the periorbital fat undergoes a pseudoherniation and pushes against the weakened orbital septum causing noticeable fat bags (Fig. 53.33).

First the brow position is evaluated. If a patient has significant brow ptosis, a brow and forehead lift must be considered and offered to the patient as a surgical option. The normal female brow is above the height of the superior orbital rim and the normal brow position in males is at the superior orbital rim. If the brows are low and the patient has significant lateral hooding, a brow and forehead lift is the proper operation, assuming the patient desires elevated brow. This not only elevates the brow and forehead, but opens up the look of the eyelids and redrapes the excess skin and fat, sometimes without any additional eyelid surgery. If the eyelid changes are severe, a brow and forehead lift and upper lid blepharoplasty may be necessary. Younger patients can often have their upper lids improved with brow and forehead lift only. If a ptotic brow and forehead go undiagnosed and the ptotic eyelid soft tissues are addressed, it can actually accentuate the problem and cause further lowering of the brows. The advice here is that all blepharoplasty patients must be evaluated for the need for brow and forehead lift and given the option. If they are candidates for the brow lift but refuse the procedure it must be well documented that they were given the option.

Cosmetic blepharoplasty is a procedure where the importance lies not in what is taken away, but rather what is left behind. If too much fat is removed, the patient can end up with a skeletonized appearance and if too much skin and muscle are removed, the patient may be unable to close the eyelids, which can lead to corneal damage and other significant functional problems. Needless to say, a patient that presents for an elective cosmetic procedure should not end up with serious cosmetic or functional problems.

Fig. 53.33 A patient with pseudoherniation of the periorbital fat pads, producing an aged and tired appearance.

Potential eyelid surgery patients must be evaluated closely as in some cases their vision can be compromised. If any patient is known to have ophthalmologic problems, they should receive a complete eye exam by their ophthalmologist with a written report back to the surgeon clearing the patient for surgery. Diabetes, thyroid conditions, uncontrolled hypertension, and other disease processes can contribute to blepharoplasty problems. All patients must also have a vision test with a Snellen chart before their procedure.

Tear production

It is paramount that patients with dry eyes be closely evaluated and conservatively treated. Should lagophthalmos (inability to close the lids completely) occur after surgery in a patient with decreased tear production, severe corneal damage could occur. When in doubt, a Schirmer test should be performed.

Potential bleeding problems

Although some surgeries can be performed with minor bleeding, blepharoplasty is not one of them. Bleeding around or behind the globe can lead to retrobulbar hematoma which can cause retinal artery occlusion and blindness.⁹ Although a rare problem, it is a reality and can be catastrophic. Patients on any medications (the list is long) that can affect coagulation must have their medications regulated. Many aspirin-containing compounds exist and the patient's co-medications must be carefully reviewed. Also, homeopathic medications and herbs such as ginkgo, ginseng, and garlic can affect hemostasis. Coagulation studies are obtained preoperatively on all blepharoplasty patients within 2 weeks of planned surgery.

Postoperative activity is also related to bleeding. Patients can induce bleeding by overactivity in the first week after surgery. It is important to have clear postoperative instructions that stress the importance of avoiding any activity that may raise blood pressure, including coughing, bending over, lifting, vomiting, etc. Patients must remain "couch potatoes" for the first 48 hours and keep cold compresses on the eyes for that time.

Eyelid laxity

Older patients or those with lax eyelids can be very problematic for the blepharoplasty surgeon, especially with lower eyelid surgery. Ectropion and associated eyelid malposition can lead to esthetic and functional problems in patients with lid laxity.

The pull test is a maneuver where the lower lid is pinched in the midline by the examiner and pulled away from the eye. A normal lower lid should stretch less than 8mm. A lower lid that pulls away from the globe 10mm or more can indicate potential problems and may require canthopexy for tightening

(Fig. 53.34). The snap test involves pulling down the lower lid with the examiner's index finger and the lid should snap back to normal position (just above the lower pupillary limbus) within 1 second. A lid that does not return to normal or one that takes longer than 1 second may indicate problematic lower lid laxity (Fig. 53.35). Novice blepharoplasty surgeons should avoid operating on patients with loose eyelids due to the potential complications.

Corneal examination

It is of utmost importance to protect the cornea at all costs during blepharoplasty procedures. Preoperative examination includes testing the corneal reflex. When the cornea is touched with a cotton-tipped applicator a blink reflex should be initiated. The eye should also be evaluated for Bell's phenomenon. When the patient closes their eyes and the examiner pries open the lower eyelid, one should see sclera, not pupil. This is a protective reflex in which the globe rolls superiorly when the eyes are shut to protect the cornea. With positive Bell's phenomenon one sees white (sclera) when the closed lid is pried open. If the patient exhibits a negative Bell's phenomenon, they are in danger of corneal damage if lagophthalmos occurs.

Fig. 53.34 The pull test measures lower lid laxity. The lower eyelid should not pull more than 7–8 mm from the globe in a normal lid.

Fig. 53.35 The snap test is another means of evaluating lower lid laxity. When pulling the lower lid inferiorly with the finger (left image), the lid should return to normal position within 1 second (right image). Failure to return to normal position or taking longer than 1 second can indicate lower eyelid laxity.

Photographic documentation

A complete preoperative photographic series is made on all blepharoplasty patients. Most patients pay little attention to their eyes until they have surgery, then they scrutinize them continually. A frontal image, bilateral oblique images, an image with the eyes closed, and an image with the patient looking superior form the minimum preoperative series. If the patient has asymmetries or other problems, pointing them out and discussing them preoperatively can save much discourse in the postoperative period. Also it is not uncommon for a patient to blame the surgeon for some problem that they actually had preoperatively, and showing the preoperative images can calm down an anxious patient.

Blepharoplasty anesthesia

Although many ophthalmologists prefer to perform blepharoplasty with an awake patient and local anesthesia, the author prefers to use intravenous sedation. It is difficult enough to operate on the eyes and having a fidgeting patient can make for dangerous surgery. Advocates of local anesthesia cite the fact that they can gauge skin removal and other indicators by asking the patient to open or close the eyes.

Blepharoplasty procedure

Many surgeons agree that learning how to properly mark the patient is actually harder than the actual surgery. As was stated previously, blepharoplasty surgery is about what is left rather than what is taken away, and this underlines the importance of correct preoperative marking.

Upper eyelid marking

The biggest challenge for novice blepharoplasty surgeons is learning how to mark eyelids properly. Once one understands the marking procedure, the surgery is relatively straightforward. If one understands correct marking technique, one understands blepharoplasty. There is no cookbook technique for marking the upper eyelid because each lid (even on the same patient) is different. It is imperative to mark the eyelids with the patient relaxed in the upright position. When the patient is lying down, the brows and lids are not in a natural position and the markings can be inaccurate. It is important to remember to take preoperative pictures before marking the patient. The lids are wiped with alcohol or acetone before marking so the ink adheres better, which preserves the markings through surgical scrub and manipulation.

The first task is to decide where to locate the upper lid crease. Most men (non-Asian) have an upper lid crease 8 mm above the lashes, and most women (non-Asian) have an upper lid crease 10–12 mm above the lashes. Generally the lid crease marking is drawn on

the patient's existing lid crease. Too high a crease in a man results in a feminine appearance, and too low a crease in a woman results in a masculine appearance. Women desire a high lid crease to have a significant lid shelf on which to apply eye shadow. The position of the upper lid crease can be discussed preoperatively; the author prefers 11 mm for women and 8 mm for men. The crease is marked by having an assistant elevate the brow to a normal position (at the orbital rim for men, above the orbital rim for women) and asking the patient to open and close the eyelid to visualize the crease. The crease is then marked from the lateral canthus to the lacrimal punctum with a fine tip surgical marker (Fig. 53.36). Generally the center of the crease is at the 8–10 mm mark, and the ends of the crease taper to 4–5 mm high, which creates an arc.

Fig. 53.36 The patient's natural eyelid crease is marked with a fine tip surgical marker. Most females have natural creases at 10–12 mm superior to the upper lid margin.

Fig. 53.37 The upper lid incision line is marked 10 mm inferior to the change in skin consistency from forehead skin to orbital skin. The lower incision line is marked 10 mm above the inferior lid margin. The skin remaining between these markings can usually be safely removed without compromising eyelid closure as long as 20 mm of lid skin is left intact.

The upper portion of the upper eyelid marking is made approximately 10 mm from the junction of the forehead and eyelid skin. If one closely examines the skin inferior to the eyebrow, one sees that there is an area (generally corresponding to the bony orbit) in which the smooth, thicker forehead skin meets the thinner crinkly upper eyelid skin. This is usually just below the finest hairs of the eyebrow. A mark is made 10 mm below this junction to define the upper extent of the skin excision (Fig. 53.37). If the surgeon leaves 10 mm from the lash to the lid crease and 10 mm from the forehead/eyelid skin junction, this gives a total of 20 mm of upper eyelid skin preserved to enable lid closure. This is the most critical point of successful upper eyelid blepharoplasty. Failure to do so can result in overexcision of upper eyelid skin and permanent lagophthalmos. One should leave at least 20 mm of upper eyelid skin intact.

The final step is to connect the incision at the lateral canthal area. If simultaneous brow lift is planned, lateral hooding of the upper lid is corrected and a “Napoleon’s hat” incision is used for the lid skin (Fig. 53.38). Because the brow lift elevates the lateral lid skin, no lateral lid skin must be excised. If a brow lift is not planned, then a “bird beak” incision is used with a lateral extension of extra lid skin excised to correct hooding (Fig. 53.39). These nicknames are used by the author to teach and are not official nomenclature in the ophthalmologic literature.

After the lid markings are made, a “pinch test” is made to check that the lids still can be closed with the prospective skin excised. When pinched, the lashes should just barely elevate, but the eyes still should be able to remain closed (Fig. 53.40). This test should be performed while elevating the brow to its normal position. This is especially critical when simultaneous brow lift is planned. Fig. 53.37 shows a summary of the planned incisions that are designed to leave a total of 20 mm of intact upper lid skin to ensure lid closure.

Fig. 53.38 When a simultaneous brow lift is performed, no significant lateral extension needs to be performed as the brow lift will elevate the lateral orbital skin and improve hooding. In this case, the “Napoleon’s hat” type of marking is made.

When addressing the medial junction of the upper and lower marks, it is important to avoid the multi-contoured depression lateral to the nose (Fig. 53.41). Generally the medial corner of this incision ends at the lacrimal punctum. If the excision is performed laterally on to the nose, a scar will be apparent and scar webbing of this multicontoured area can occur. Again, one must remember to elevate the eyebrow to a normal position before making the incision markings.

Upper lid incision

The author wears three-power surgical loupes and a headlight for all blepharoplasty procedures. Hemostasis is the key to safe blepharoplasty. When fat pads are recontoured, it is not unusual for a lacerated blood vessel to retract deep into the orbit and it can be challenging to cauterize it. If this occurs with a cut, bleeding vessel, it could cause a retrobulbar hematoma. Sometimes these vessels are small, and wearing loupes is a significant advantage. Many

Fig. 53.39 When no brow lift is planned, the lateral portion of the excision is usually angled up on the inferior margin and produces an angular geometric incision marking on the lateral region in order to remove extra skin to improve hooding. In this case the “bird beak” incision marking is made.

Fig. 53.40 After all markings are made, the incision margins are pinched together and the upper lash should just begin to elevate.

other small structures must be avoided, and the use of surgical magnification and concentrated headlight instruments cannot be overstated.

Incisional modalities for the upper eyelid skin include scalpel, scissors, radiofrequency microneedle tip, and laser. The author routinely uses either CO₂ laser or radiofrequency for upper blepharoplasty. Fig. 53.42 shows a picture of the 0.2mm laser handpiece for the Lumenis Encore CO₂ laser and the Ellman radiofrequency system with the Ellman Empire Micro Incision Needle. These modalities, especially the CO₂ laser, produce minimal bleeding, which translates into fewer complications and faster recovery. The author has conducted research using a CO₂ laser cutting handpiece with a 0.2mm spot size on one upper eyelid and the Ellman radiofrequency microneedle on the other upper lid. Basically, these instruments perform similarly and produce scars that cannot be differentiated in a statistically significant manner by blinded observers.¹⁰ The CO₂ laser is more efficient at hemostasis but is less effective on a large bleeding vessel. It is rare for the author to cause a cotton swab-sized amount of blood loss in routine blepharoplasty (Fig. 53.43).

Once the upper lid has been marked, prepared, and anesthetized, a full-thickness skin ellipse is excised. This skin is thin, and one must ensure that only the skin is dissected, similar to peeling a grape skin. This plane may be “predissected” by spreading a tenotomy scissors between the skin and muscle plane. Once the skin ellipse is removed, the orbicularis oculi muscle is visualized. This muscle is vascular and frequently has a superficial network of large vessels on its surface. The next step is to excise and sculpt the orbicularis muscle. Some surgeons advocate removing the same amount of orbicularis as skin. The author has found that being more conservative in muscle resection results in a better sculpted lid sulcus, faster return of eyelid function, and less bruising. Four to five millimeters of orbicularis oculi muscle

Fig. 53.41 It is important to not extend the upper incision on to the multicontoured areas (circled) of the medial orbital/nasal region or an unsightly and difficult to correct webbed scar can occur.

Fig. 53.42 The 0.2mm CO₂ laser handpiece and the radiowave surgery system are pictured.

Fig. 53.43 This author utilizes radiofrequency microneedle or CO₂ laser for blepharoplasty incision. This image shows the bloodless excision of the upper lid skin with either modality.

Fig. 53.44 The orbicularis oculi muscle in the upper eyelid being resected with laser and radiofrequency modalities.

are excised using either the CO₂ laser or the Ellman radiofrequency microneedle (Fig. 53.44).

If the orbicularis oculi muscle is dissected in the proper plane, the orbital septum is visible. It is frequently translucent, and one can see the fat pads moving under the septum during light pressure on the globe. The septum can be incised with a small rent over the central and medial fat pads or incised totally from medial to lateral. For the novice surgeon, the orbital septum may not be apparent, and there is risk

of incising through the levator aponeurosis (and deeper structures) if the incision is placed too inferiorly. When in doubt as to where the upper lid fat pads are located, one should err in the direction of the superior orbital rim. These fat pads cushion the globe between the bony orbit and anatomically are close to the orbital rim. Gentle pressure on the globe (retropulsion) accentuates the prolapsed fat pads and makes them more visible. The septum is incised with the CO₂ laser or Ellman radiofrequency microneedle

in the center of the orbit just below the orbital rim. The central fat pad generally prolapses and can be dissected to its lateral extent, which sometimes may extend to the lateral portion of the incision. The lacrimal gland lies in the superior lateral portion of the orbit and has been mistaken for fat pads. There are usually only two fat pads in the upper eyelid: a central and a medial. The lacrimal glands are pinker (similar to parotid tissue) and firmer than the yellow central fat pad. If the lacrimal glands are slightly prolapsed, they can be tucked back into the orbit. If they are significantly prolapsed, they are suspended to the orbital periosteum with a non-resorbable suture.

Many surgical techniques exist to reduce or recontour the orbital fat pads. Whatever technique is used, the surgeon must pay close attention not to pull, stretch, or retract the fat pads too much. Many vessels traverse the fat pads from deep within the orbit. If the fat pads are overstretched from the orbit, one could lacerate a deep vessel. When the fat pad is released it can retract deep into the orbit along with the bleeding vessel. If uncontrolled bleeding occurs deep in the orbit, a hematoma can form and compress the retinal artery and cause permanent blindness. Extreme caution should be used when handling the fat pads. Generally, one should excise only the amount of fat that easily protrudes with gentle pressure on the globe. The surgeon or the assistant never should “tug” on the fat pads. Sometimes a surgeon views the fat pads as the “enemy” and removes as much as he or she can find. Blepharoplasty is an operation of what tissue is left behind, not what tissue is removed. Excessive fat resection causes a hollow-looking orbit, which gives the patient an older, gaunt appearance. One should be conservative. A good general rule is to take only the amount of fat that the orbit “gives up” and not be overly aggressive in searching for or removing deep fat. Some surgeons prefer “melting” the fat pads with laser or radiofrequency instead of resecting or recontouring portions of the fat pad. Fat pad removal has been described as teasing out the protruding fat then clamping the base of the fat pad with a hemostat before resecting. Although it makes sense to clamp and crimp the base of the fat pad to assist in hemostasis, the hemostat also can exert a lever effect on the fat pad and inadvertently stretch the base of the fat pad and lacerate a vessel. This can

Fig. 53.46 Clamping the base of the fat pad with a small hemostat can assist hemostasis before sectioning the base of the fat.

happen when the assistant holds the hemostat while the surgeon incises the fat pad. When the CO₂ laser or the Ellman microneedle tip electrode is used, excellent hemostasis ensues and the clamp is not required (Fig. 53.45). If a surgeon wishes to excise fat with a scalpel or scissors, the use of a clamp is recommended before cutting to ensure hemostasis. Cauterizing the base of the fat pad above the hemostat also is recommended before release (Fig. 53.46).

Locating the medial fat pad in the upper eyelid can be a challenge for the novice surgeon. It usually lies more medially than the medial incision. The best means of locating the medial fat pad is to spread a small hemostat gently in the inferior medial portion of the medial blepharoplasty incision while gently pressing on the globe. This should be done delicately, with small spreading motions. Once the medial fat pad is located and teased out, it frequently balloons to surprising proportions. The medial fat pad contains a larger amount of fibrous tissue than the other

Fig. 53.45 The CO₂ laser and radiowave microneedle produce a safe and bloodless modality for fat excision in upper lid blepharoplasty.

fat pads and is usually a whiter color when compared with the butter yellow color of the other fat pads. As fat is removed from each eye, it is placed on a gauze or towel so that approximately similar volumes are removed from both eyes.

Once the medial and central fat pads are recontoured, the entire surgical site is reinspected for bleeding. Placing several drops of saline or local anesthesia in the incision site can help identify small or persistent bleeders. Once the surgeon is sure that the surgical field is dry, the incision is closed with either 6/0 nylon or 6/0 fast-absorbing gut suture in an interrupted or running fashion. If a lateral extension is used on the blepharoplasty incision, several interrupted sutures are placed to reinforce the tissue in the crow's feet areas. An interrupted or running 6/0 nylon suture is used for the remaining closures (Fig. 53.47). When performing simultaneous upper and lower blepharoplasty, the lower lids are usually done first so as not to disturb the upper incisions with retraction suture. The surgical site is then covered with triple antibiotic ointment and iced saline gauze. If nylon sutures are used, they are removed at 5 days. It is much easier to remove a single running suture than 10–12 interrupted sutures.

Lower eyelid transconjunctival technique

The transconjunctival approach for lower eyelid fat removal does not violate the orbital septum and produces less lower lid retraction. Some surgeons use the transconjunctival approach and perform a preseptal dissection, which requires septal incision and negates the septal sparing component of this approach. The surgical approach described is retroseptal. Using the thumb and index finger, the assistant retracts the lower eyelid. The surgeon gently depresses the globe with a Jaeger lid plate retractor, which prolapses the herniated fat. Technically the incision should be made approximately 4 mm inferior to the lower tarsal margin or approximately 8 mm from the lower lid margin.

Fig. 53.47 Closure of upper blepharoplasty incision with several spaced interrupted sutures followed by a running 6/0 fast-absorbing gut suture. All sutures are removed at 5 days.

(Because the lower tarsus is approximately 4 mm wide, placing the incision 4 mm below this equals 8 mm.) The incision is made directly through the middle of the conjunctival bulge that forms from the assistant's retraction and the surgeon's pressure from the Jaeger lid plate. This usually corresponds to 4 mm below the inferior tarsal margin. If in doubt, one should err in the direction of the orbital rim and not the globe. A transconjunctival incision too deep in the fornix can damage the extraocular muscles and initiate unnecessary bleeding. The incision is made from the lacrimal punctum medially to the lateral canthus laterally. Failure to carry the incision far enough laterally causes the surgeon to operate in a hole and makes surgery more difficult, especially access to the lateral fat pad. To allow access to the lateral canthal conjunctiva, the assistant must move the thumb and index finger more laterally to pull and spread the lateral canthus. Doing this provides access to the conjunctiva in the lateral corner of the eye. The CO₂ laser or Ellman microneedle is used to incise through conjunctiva and capsulopalpebral fascia (lower lid retractors) in gentle, sweeping motions (Fig. 53.48).

At this point, a retraction suture is placed. A 5/0 gut suture on a small cutting needle is passed through the superior incision margin and draped over the head and suspended with the weight of a hemostat (Fig. 53.49). This technique retracts the incision for facilitated view and instrumentation. It also can serve to protect the globe.

After each level of incision, the fine hemostat is inserted and right-to-left spreading is done gently (as opposed to anterior–posterior spreading, which could damage the eyeball). One must pay attention to staying anterior to the globe when incising and dissecting. In some patients these layers are thick and well defined, and the surgeon can incise directly to the fat pads. In other patients the anatomy is less defined, and accessing the fat is a matter of gentle incision and gentle spreading with the small hemostats. As this gentle dissection is performed, gentle pressure is

Fig. 53.48 Incision placement of the transconjunctival approach from the surgeon's view. The incision is made from the punctum to the lateral canthus about 4 mm below the lower tarsal margin or 8 mm inferior to the ciliary margin.

Fig. 53.49 A retraction suture is placed through the superior incision flap, secured with a hemostat and hung over the head to retract the incision.

placed on the globe and the fat pads come into view. If the surgeon becomes disoriented or unsure of his or her position within the orbit, he or she should use an instrument to sound the inferior orbital rim. This ensures that the surgeon's position is anterior to the globe. As the fat pads come into view, their capsule is incised by laser or radiofrequency, which usually allows the herniated fat to billow out of the incision (Fig. 53.50). The fat is teased out and never stretched or pulled with significant traction as a vessel may be torn or lacerated.

The lower lid fat is incised with laser or radiofrequency electrode (Fig. 53.51). The central fat pad is usually the first encountered and the easiest to reduce. The medial fat pad, as in the upper lid, frequently takes some blunt dissection to locate, but once incised it gives up an impressive amount of fat. This fat is more fibrous and a whiter color. The lateral fat pad in the lower lid may be difficult to deliver into the surgical field, and some exploration may be necessary. It is usually located more laterally than the lateral extent of the transconjunctival incision. The surgeon should look continually at the external lid skin while pressing on the globe to verify adequate fat removal. The inferior oblique muscle divides the central and medial fat pads, and this muscle is sometimes encountered in

lower transconjunctival blepharoplasty (Fig. 53.52). The muscle is best avoided, with care taken not to incise it. It is not a problem to retract the muscle gently, but damage could result in extraocular muscle dysfunction.

After the three lower fat pads have been recontoured, the surgical site is checked for hemostasis.

Fig. 53.51 A radiowave microneedle electrode being used to cauterize the base of the medial fat pad. The excess fat is excised slowly and conservatively in a bloodless manner with this modality or with CO₂ laser incision.

Fig. 53.50 The medial, central, and lateral lower fat pads teased out of their respective positions into the transconjunctival operative field.

Fig. 53.52 The inferior oblique muscle divides the medial fat from the central fat compartment and is frequently encountered in the transconjunctival approach.

Generally the incision is not closed unless it is gaping. Usually by picking up the incision margins with small forceps and approximating them, they stay together well and rarely, if ever, require suturing (Fig. 53.53).

It should be noted that some contemporary surgeons do not advocate any fat removal and they instead reposition the bulging fat over the inferior orbital rim. This is done to reduce the fat bags without creating hollows. The author has little experience with fat repositioning and prefers conservative fat removal.

The next step is to address the dermatochalasis of the lower eyelid. The author's preference is CO₂ laser resurfacing of the periorbital areas. The Lumenis (formerly Coherent) ultrapulsed Encore laser (Santa Clara, CA) with a computer pattern generator is used. For periorbital resurfacing, a setting of 80 MJ, 600 Hz, and a number 1 pattern (circle) size 6–7 and a density of 6 (30% overlap) is selected. A full pass is made over both eyelids and crow's feet areas, if required (Fig. 53.54). A second pass is then made on the lower lids only.

It is hard to conceal laser redness outside the confines of the orbital rims. Inside the confines of the orbital rims, the treated and untreated junction is not as obvious and can be covered with sunglasses. If a patient wants resurfacing of the crow's feet and infra-orbital areas, the author frequently converts this to a full-face resurfacing procedure to better blend the laser areas and not end up with relative hypopigmentation of the treated skin when compared with the surrounding skin. After the first pass, the char is debrided with moist gauze followed by dry gauze. A second pass is made on the lower lid at the same or lower setting. Frequently only a single pass is used on the upper lids to blend the color. This is especially true if blepharoplasty and brow lift are performed together. Adding aggressive laser resurfacing with other procedures can cause lagophthalmos. If severe wrinkling exists, two passes are used on the upper lids. It is important to understand that there is no

Fig. 53.53 The transconjunctival incision is passively approximated at the end of the procedure and does not require suture closure.

definitive laser setting and that each laser and each patient involve separate situations and must be treated individually. The second pass is then debrided with the moist and dry gauze and a petrolatum dressing is applied. The laser shields are removed, and the eyes are copiously irrigated with basic saline solution and lubricated with bacitracin ophthalmologic ointment.

When performing blepharoplasty on four lids simultaneously (or sometimes two lids), a patient may have several millimeters of lagophthalmos (inability to close the eyelids completely). This is not unusual and results from swelling, local anesthesia, local hemorrhage, and tissue traction. It usually resolves in several days or a week.

Skin pinch technique

If the laser is not used, the skin pinch technique is indicated. The author tries to avoid using a skin-muscle approach to preserve the orbital septum and prevent lower lid retraction.

The skin pinch technique is a convenient, minimally invasive procedure that deals with excess skin in the lower eyelid.¹¹ It also complements the transconjunctival approach for individuals who cannot tolerate post laser erythema. The author uses this technique mostly in men or patients with pigmented skin for whom the laser is contraindicated. Women can cover laser redness with makeup, but because erythema can persist for months, it is prohibitive in many men. African-American, Asian, Latino, or other individuals with pigmented skin tend to have post-laser pigmentation problems, and the skin pinch technique is a favorable adjunct for that population. The procedure is simple and involves crimping the excess skin with a hemostat and resecting the skin.

If intravenous sedation is used, no local anesthesia is required with this technique. In a non-sedated patient, local anesthesia infiltration is required, but it distorts the skin and makes the judgment of how much skin to remove more difficult.

Fig. 53.54 The excess periorbital skin is treated with the CO₂ laser.

The skin pinch is performed last, after completing the transconjunctival removal of herniated periorbital fat. The first step is to take cotton pliers and grasp the excess lower eyelid skin just below the lashes (Fig. 53.55). Generally, most patients require approximately 5 mm of skin to be removed (Fig. 53.56). By “test pinching” with the cotton pliers, the surgeon can judge how much skin to remove. The skin is pinched just below the lash so that the lower lid skin is tightened while the lower lashes are gently everted without retracting the lower eyelid. When satisfied with the correct amount of skin (one should be conservative), the pinching begins in the lateral one third of the lower lid.

Using a small hemostat, the surgeon pinches 4–5 mm of excess skin and crushes it in the serrated beaks of the hemostat at the nasal, central, and lateral regions (Fig. 53.57). The surgeon must grab and crush the same piece of skin three to four times. Doing this elevates a ridge of excess skin that is crushed at its base. The next step is to use a Wescott or other small scissors to sever the crushed skin ridge at its base (Fig. 53.58). Little bleeding occurs due to the fact that the base of the incision is crimped. The surgeon needs to be careful not to cut the eyelashes when trimming

the skin. After the scissor excision the crushed skin stays approximated as shown in Fig. 53.59.

The incision can be pulled apart, which exposes the orbicularis oculi muscle in the lower eyelid. If the muscle is hypertrophic, the surgeon can trim the excess or shrink it with the CO₂ laser or Ellman radio-frequency small ball electrode (Fig. 53.60).

Because the skin has been crushed and cut at several points, a jagged incision may result. The Ellman

Fig. 53.55 The excess skin of the lower lid is pinched with a forceps to estimate the amount to be resected.

Fig. 53.56 Skin excision of the pinch procedure should be very conservative so as not to cause lower lid malposition. Generally the amount of skin excised is 3–6 mm.

Fig. 53.57 Curved hemostats are used to crush the lower eyelid skin at the nasal, central, and medial regions.

Fig. 53.58 The crushed skin is then excised with microscissors at the base.

Fig. 53.59 The excised skin and the resultant wound.

Empire radiofrequency microneedle can be used to even out the incision to a semilunar shape. The final step is to close the incision with five to six 6/0 fast-absorbing gut sutures (Fig. 53.61).

Skin-muscle approach for lower blepharoplasty

Although this approach to the lower eyelid is very popular with some surgeons, the author tries to avoid it because of the increased incidence of lower lid malposition. There are times when a patient has hypertrophic orbicularis oculi muscle bulges in the lower lid and this technique is required.

The periosteum of the lateral orbital rim is contiguous with the orbital septum. Local anesthesia is injected at the lateral orbital rim, the needle is angled parallel to the lower lid margin and the plane between the septum and orbicularis muscle is ballooned with local anesthesia. An incision is made at the lateral canthal area and fine scissors are used to dissect bluntly to the periosteum over the lateral orbital rim. Once this plane is reached, the scissors are turned sideways and the ballooned plane between the septum and the muscle is dissected easily by spreading

the scissors from the lateral lid to the medial lid (Fig. 53.62).

The next step involves angling the scissors parallel to the lower lid and making a cut through the skin and muscle (Fig. 53.63). The scissors are repositioned parallel to the skin, and the skin and muscle are cut on an angle, with the outside limb of the scissors cutting the skin surface and the inside limb of the scissors cutting the muscle surface. The muscle is cut at a higher level than the skin, which preserves the pretarsal muscle structure and decreases the chance of lower lid ectropion.

When the subciliary incision is completed, the surgeon has an excellent open view of the orbital septum (Fig. 53.64). The septum is incised by the preferred modality (Fig. 53.65), and the three lower fat pads are identified and recontoured (Fig. 53.66). The final and trickiest step is trimming the excess skin and muscle from the lower incision margin. This is described in many ways by various authors and is often contradictory. The author has found the following technique to work effectively without causing lid retraction. The excess skin is grasped and pulled superiorly and slightly laterally at the lateral orbital rim area. There is more superior pull than lateral. This approach pro-

Fig. 53.60 The orbicularis oculi muscle can be contracted by using the radiowave ball electrode or the CO₂ laser. This can provide further tightening for the procedure.

Fig. 53.61 The skin pinch incision is closed with 6/0 fast-absorbing gut suture.

Fig. 53.62 The scissors are inserted above the septum and below the orbicularis muscle and the plane is easily dissected by spreading and advancing the scissors.

Fig. 53.63 The skin incision is made with scissors in a curvilinear line in the subciliary region.

duces a triangle of excess lower lid skin and orbicularis muscle. The triangle is pulled with minimum traction to prevent over resection, and the base of the triangle is trimmed (Fig. 53.67). The skin is then closed with 6/0 nylon or 6/0 fast-absorbing gut sutures. The septum is never sutured.

Postoperative care

Postoperative care is centered on keeping activity and blood pressure down. Catastrophic complications, including blindness, can occur from retrobulbar hematomas causing retinal artery occlusion. Iced saline gauze (or commercially available cold packs or gel masks) are immediately applied and left on for 24–48 hours. The author makes all patients promise to be a “couch potato” for 48 hours and sleep with their head elevated. It is imperative that they do not perform Valsalva maneuvers or otherwise increase blood pressure to the head. Retrobulbar bleeds have occurred from coughing, straining with bowel movements, bending over, sexual intercourse, and other exertion in the immediate postoperative period. Patients are instructed not to lift anything over 5 kg for 1 week. It is also important to ensure that patients refrain from any medication that may prolong bleeding. Postoperative care includes antibiotics, analgesics, tapering steroids, and ophthalmic drops (Tobradex or Oculoflox) on occasion. Patients can expect swelling and sometimes bruising. Pain is gen-

erally minimal unless corneal abrasion has occurred from eye shields. Patients should be able to see light and count fingers. Severe pain, throbbing retrobulbar pain, or frank proptosis may signal retrobulbar hematoma and should be immediately assessed because it indicates a true emergency.^{12,13} If all four lids are operated or if endoscopic brow lift or periorbital laser is performed, the eyelids may swell shut for 24 to 48 hours. Patients should receive preoperative instruction regarding that possibility.

Some patients cannot close their eyes completely after blepharoplasty; this condition usually resolves

Fig. 53.66 The exposed fat pads are conservatively excised and recontoured, in this case with the Ellman radiowave microneedle electrode.

Fig. 53.64 The orbital septum and underlying fat are visualized after the suborbicularis dissection is performed.

Fig. 53.67 The excess skin is conservatively trimmed. The novice blepharoplasty surgeon should always excise skin conservatively, so as not to cause lower lid malposition.

Fig. 53.65 The orbital septum is incised and the fat pads are accessed under direct vision.

Fig. 53.68 A patient with subconjunctival ecchymosis. The patient did not stop aspirin preoperatively as directed. The situation spontaneously resolved in 10 days.

spontaneously in several days to several weeks. One problem is dry eyes caused by lagophthalmos, which can be painful and irritating and, in severe cases, may cause corneal problems. The author uses Refresh eye drops (Allergan, Irvine, CA) for these patients during the day and Refresh Plus eye drops at night. Generally they adequately hydrate the eye until the lagophthalmos resolves. If dryness is severe, especially at night, patients can cut a piece of plastic wrap the size of their palm and cover their eye at night. Applying

petroleum jelly or lotion to the periorbital area keeps the plastic wrap in place.

Another common complication is subconjunctival ecchymosis (Fig. 53.68). This harmless complication is a result of blood under the bulbar conjunctiva. Patients should be reassured that this condition will resolve, although sometimes it can last several weeks.

Chemosis is edema of the bulbar conjunctiva and may be caused by inflammation or overactivity. The patient in Fig. 53.69 felt so good after her blepharoplasty that she went home and bent over to pull weeds, which caused severe chemosis. She was treated with prednisone, 60 mg once a day, for 5 days and warm compresses. The chemosis resolved within a week.

Periorbital ecchymosis can occur for no apparent reason, but may signal a coagulation problem. The patient in Fig. 53.70 had normal coagulation studies but a history of bruising. Periorbital ecchymosis resolves spontaneously.

Postblepharoplasty wound dehiscence can occur, and unlike other surgical wounds it usually heals without any significant scarring. If the wound separates in the first 48 hours, it can be cleansed and resutured. Late wound dehiscence is treated by wound care with irrigation and topical antibiotic ointment. Fig. 53.71 shows an early wound dehiscence that was cleansed and resutured. Fig. 53.72 shows a late wound dehiscence. At 3 months, the scar

Fig. 53.69 Chemosis is conjunctival edema that can occur from postoperative overactivity and responds to rest, heat, and corticosteroid treatment. This patient is shown preoperatively, 5 days postoperatively with severe chemosis, and 3 weeks postoperatively after rest, heat, and prednisone treatment.

Fig. 53.70 Periorbital ecchymosis can be caused from coagulation problems. Some patients are prone to such bruising despite normal coagulation profiles. Aspirin or other medications that affect platelet function can also contribute.

Fig. 53.71 Suture line dehiscence that occurs in the first several days of healing can be cleansed and reclosed.

Fig. 53.72 This late-occurring suture line dehiscence (12 days) healed by secondary intention without significant scarring.

Fig. 53.73 This male patient is shown 8 weeks after bilateral upper blepharoplasty, bilateral lower transconjunctival blepharoplasty, and periorbital CO₂ laser skin resurfacing. The significant improvement in skin wrinkling is a direct result of the laser treatment.

Chapter 54

Diagnosis and Non-surgical Management of Orofacial Pain

Charles McNeill and Patricia A. Rudd

This chapter will cover the classifications and descriptions of orofacial pain syndromes, both intraoral and extraoral. Appropriate imaging studies for orofacial pain syndromes and temporomandibular joint disorders will be discussed. The diagnosis of both intra-articular and extra-articular temporomandibular disorders is discussed together with non-surgical management of temporomandibular joint disorders, including behavioral therapy, physical therapy, pharmacological management, and orthopedic appliance therapy.

Introduction

Successful orofacial pain diagnosis begins with the clinician understanding the current principles of basic pain mechanisms. In order to fulfill this important responsibility, the dentist must have a working knowledge of functional neuroanatomy, peripheral and central nervous system pain pathways, including the descending pain modulating system, and the affective or emotional aspects of persistent pain.¹⁻⁴ Pain is defined as an unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage by the International Association for the Study of Pain.⁵ The definition of pain avoids relating the pain directly to the stimulus. A pain experience reported

in the absence of tissue damage is accepted as pain in the same way as pain clearly related to tissue damage.

Pain is subjective and is a personal experience that cannot be shared, involving both sensation and emotion. A stimulus is referred to as a noxious stimulus when it is one that is damaging to normal tissues. Pain responses to a given stimulus cannot be predicted with any degree of certainty. Noxious stimuli elicit a variety of behaviors that not only serve to protect uninjured tissues, but that can also cause affective or unpleasant behavioral aspects of pain. This variability is related to the activity of the pain modulation system in the central nervous system (CNS). Dysfunction of the nervous system can cause hypersensitivity and variations in pain tolerance. Pain tolerance, the

greatest level of pain which a subject is prepared to tolerate, is highly variable and depends on personality traits and situational factors. Individuals apply different meanings to pain and develop different ways to cope with pain. For example, cultural differences can lead to learned pain behavior as can other behavioral and psychological factors.

Pain can be either acute or persistent (chronic). Acute pain has a recent and usually sudden onset with short duration limited to the normal healing time. The development of acute nociceptive (normal) pain may be due to inflammation, mechanical deformation, ongoing injury, or destruction of tissue. Acute pain is usually self-limiting and does not typically present a diagnostic problem. The patient understands the cause and effect of the pain, and the clinician usually renders the appropriate intervention to treat the condition. Sometimes pain persists or even becomes worse beyond the expected time of healing. Historically the pain conditions that last longer than 3 months, regardless of the mechanism, have been referred to as chronic pain conditions or syndromes, but today the preferred term is non-malignant persistent pain. The onset of non-malignant persistent pain is less well defined than that of acute pain. Persistent pain conditions are not easily understood by the patient or the clinician and become pain without meaning.⁶

The multitude of disease entities that can present with similar pain patterns in the head, face, and neck region mandate that clinicians consider diseases unrelated to the masticatory system in their differential diagnosis of orofacial pain. A thorough diagnostic process using validated diagnostic criteria is critical, because an incorrect or omitted diagnosis is one of the most frequent causes of treatment failure.⁷ It, in fact, becomes a daunting task to correctly identify all of the possible sources of pain that may be the cause, the effect or are coincidental to a patient's orofacial pain complaints. In order to help differentiate all the possible head, face, jaw, intraoral, and neck pain conditions, it is essential to have a systematic approach. Internationally established pain classifications with operational diagnostic criteria for the various possible orofacial pain conditions serve as useful guides. Differential diagnoses can at least be based on universally accepted inclusion and exclusion criteria, even though the mechanism causing the pain may not be fully known.

Head, neck, and orofacial pain classifications

In 1988, the International Headache Society (IHS) published its landmark diagnostic system, the *Classification and Diagnostic Criteria for Headache Disorders, Cranial Neuralgias and Facial Pain*.⁸ This classification system, with specific operational diagnostic criteria, was updated and improved in 2004 and was

entitled the *International Classification of Headache Disorders II (ICHD-II)*.⁹ Two years after the publication of the second edition, the IHS launched a website edition of the International Classification of Headache Disorders (ICHD-II) (Table 54.1).¹⁰ In support of, and in conformity with this major effort, the American Academy of Orofacial Pain (known as the American Academy of Craniomandibular Disorders at the time) published a diagnostic classification for temporomandibular disorders (TMD) in 1990.¹¹ The American Academy of Orofacial Pain (AAOP) improved this classification in 1993 with the addition of more specific inclusion and exclusion diagnostic criteria.¹² In 1996 and recently in 2008, the AAOP diagnostic classification has been expanded based on the IHS classification, to include all head, face, and neck conditions that could be associated with orofacial pain.^{13,14} This classification is, as is the International Headache Society's genitor classification, a work in progress with plans to publish updated editions as new research mandates a timely transfer of science.

This chapter presents an overview of the diagnosis of orofacial pain and the specific management of temporomandibular disorders (TMD). The diagnostic range of orofacial pain includes the following three

Table 54.1 The International Classification For Headache Disorders (2nd edition: ICHD-II).

Part 1	Primary headaches
IHS 1	Migraine headache
IHS 2	Tension-type headache
IHS 3	Cluster headache and other trigeminal autonomic cephalgias
IHS 4	Other primary headaches
Part 2	Secondary headaches
IHS 5	Headache attributed to head and/or neck trauma
IHS 6	Headache attributed to cranial or cervical vascular disorder
IHS 7	Headache attributed to nonvascular intracranial disorders
IHS 8	Headache attributed to a substance or its withdrawal
IHS 9	Headache attributed to infection
IHS 10	Headache attributed to disorder of homeostasis
IHS 11	Headache attributed to extracranial pain disorders
IHS 12	Headache attributed to psychiatric disorder
Part 3	Cranial neuralgias, central and primary facial pain
IHS 13	Cranial neuralgias and central causes of facial pain
IHS 14	Other headache, cranial neuralgia, central or primary facial pain

categories: (1) medical conditions that either directly cause, refer pain to the region, or masquerade as orofacial pain; (2) intraoral pain conditions; and (3) musculoskeletal pain conditions affecting the neck and jaw (Table 54.2). Medical conditions that can be associated or confused with orofacial pain include intracranial non-vascular and vascular disorders, neurovascular pain conditions (primary and secondary headache), neurogenic (neuropathic) pain conditions, and extracranial pain disorders (e.g. ear, nose, sinus, throat conditions). Extracranial intraoral pain disorders include hard and soft tissue conditions (teeth and supporting bone), mucogingival and glossal pain, and salivary gland pain conditions. Extracranial musculoskeletal conditions involve both the neck and jaw. The jaw conditions are commonly referred to as temporomandibular disorders (TMD), and they include temporomandibular joint (articular) and masticatory muscle (non-articular) disorders.

Medical conditions masquerading as orofacial pain

Intracranial disorders

Disorders of the intracranial structures, such as neoplasia, aneurysm, abscess, hemorrhage or hematoma, and edema can usually be easily differentiated from orofacial pain.¹⁵ They should be considered first in the diagnostic process, because they can be life threatening and require immediate attention. The characteristics of serious intracranial disorders include new or abrupt onset of pain, pain that increases in severity, interruption of sleep by pain, pain precipitated by exertion or positional change, and neurologic deficits. Referred pain from primary and metastatic tumors in

particular can be extremely difficult to separate from symptoms related to temporomandibular disorders in a timely manner. The referred pain is particularly difficult to distinguish from tempomandibular disorder signs and symptoms in the earlier stages of the various disease entities.¹⁶ One vascular pain disorder, temporal arteritis, a giant cell arteritis, may be misdiagnosed as myofascial pain involving the temporalis muscle. The patient, typically at least 60 years of age, presents with a fever, anorexia, loss of weight, and severe headache. The temporal and possibly the facial arteries are swollen, torturous, and extremely tender. Arteritis is associated with a significantly elevated erythrocyte sedimentation rate, and biopsy of the temporal artery confirms the diagnosis. Treatment consists of the appropriate corticosteriod therapy for the autoimmune inflammatory process. If treatment is delayed, temporal arteritis can quickly lead to a loss of vision due to acute ischemic optic neuropathy secondary to inflammation of the ciliary artery.¹⁷

Neurovascular headache disorders

Headache is a common complaint reported by patients suffering from musculoskeletal jaw disorders. Neurovascular headache disorders and jaw disorders can share common nociceptive pathways, therefore clinicians must be aware of the characteristics of primary and secondary headache and their potential association with orofacial pain.¹⁸

Primary headache

Primary headache disorders associated with orofacial pain include migraine headaches, migraine-variant headaches, cluster headaches, chronic paroxysmal hemicrania, and tension-type headaches. Migraine headache is divided into migraine with aura (classic) and migraine without aura (common migraine) headache. Migraine with aura headaches are characterized by unilateral (60–70% of the time), throbbing or pulsating pain lasting 4–72 hours with frequent accompanying nausea and/or vomiting, phonophobia, and photophobia. They typically have a prodromal phase with visual aberrations. Migraine without aura is similar to classic migraine, but proceeds into headaches without a prodromal phase. Tension-type headaches are believed to be a type of chronic or episodic migraine-like headache. They are bilateral, mild to moderate in intensity, and characterized by a non-pulsating, pressing, or tightening feeling in the head. The headaches are not related to the use of the jaw such as chewing hard foods, and may be associated with pericranial muscle tenderness. It is important to distinguish between tension-type headaches and localized myofascial pain of the temporalis muscles. The symptoms of these conditions can be very similar, but the source of the pain can be quite different requiring very different management strategies.¹⁹ It is reported that orofacial pain patients have greater

Muscular disorders

prevalence of primary headaches with a greater disability impact than non-orofacial pain subjects.²⁰ Future headache therapeutic targets need to address genetics and neurophysiologic changes in the neurons and brain and also help to control immune systems including the glia that support neuronal cell function, protecting and aiding the repair and regeneration of damaged neurons.²¹

Secondary headache

Secondary headache disorders are defined as headaches that develop secondary to another condition or mechanism. These could include physical exertion, cold stimuli, trauma, infection, metabolic disorders, or substances or substance withdrawal. Orofacial pain can commonly be associated with rebound headache. Patients who have misused or abused medications, including over-the-counter analgesics and non-steroidal anti-inflammatory drugs, can suffer from rebound headache. When prescription medications are either prescribed or taken inappropriately, or when patients develop tolerances to the medications, breakthrough pain can become a major problem. There is usually a history of daily or near-daily headache and medication use, associated depression and sleep disturbance, and occasional severe migraine-like attacks. The possible mechanism of rebound headache is related to interference of the descending pain modulation system and neuroplasticity changes in the CNS by inadequate pain control from improper pharmacotherapeutic strategies.²²

Neuropathic pain disorders

Neuropathic pain is a disorder resulting from injury, peripheral and/or central, in the pain transmission system and is usually present in the absence of an ongoing primary source for the pain.²³ Neuropathic pain disorders are divided into either paroxysmal (episodic) or continuous painful conditions.²⁴

Paroxysmal disorders

The paroxysmal conditions associated with orofacial pain include the following: trigeminal neuralgia, glossopharyngeal neuralgia, and the more rare conditions of nervous intermedius neuralgia and superior laryngeal neuralgia. Occipital neuralgia involving the greater and lesser occipital nerves with occasional persistent pain between the paroxysmal episodes can be a source of headache. The pain sensations follow the distribution of these different nerves and are characterized by brief electric shock-like (lancinating or jabbing) pains lasting only seconds to minutes with pain-free intervals. One of the distinguishing aspects of trigeminal neuralgia and glossopharyngeal neuralgia is that the pain is evoked by trivial stimuli including use of the jaw (e.g. talking, swallowing, or even brushing the teeth) as well as just lightly touching the

face or mouth. Typically the second and third divisions of the trigeminal nerve are affected; the first division is only affected in 1–2% of the patients. The unilateral pain is severe with remissions lasting for days to years. Glossopharyngeal neuralgia pain is also a severe, transient, stabbing or burning pain located in the ear, base of the tongue, tonsillar fossa, or beneath the angle of the mandible. The paroxysms of pain are provoked by swallowing, chewing, talking, or yawning. Glossopharyngeal neuralgia is 50–100 times less common than trigeminal neuralgia.

Continuous disorders

The continuous neuropathic pain disorders associated with orofacial pain are primarily deafferentation pain syndromes related to compression or distortion, demyelination, infarction, or inflammation of the cranial nerves. Acute herpes zoster, chronic post-herpetic neuralgia, diabetic neuropathy, and neuromas are examples of continuous neuropathic pain syndromes. Burning mouth syndrome (BMS) is considered a neuropathic pain. The pain is persistent without major visible signs of spontaneous onset. Idiopathic persistent facial pain, historically referred to as atypical facial pain, is likely related to partial or complete deafferentation.²⁵ The previously mentioned atypical odontalgia or idiopathic odontalgia (historically referred to as phantom tooth pain) is a continuous, but variable, dull ache that sometimes is also described as a burning pain that typically follows dental treatment.²⁶

Headache attributed to associated extracranial pain disorders

Extracranial pain disorders associated with orofacial pain include pain related to the eyes, ears, nose, sinuses, throat, intraoral structures, neck, jaw, and cranial bones (Table 54.3).²⁷ The site of pain in the head, neck, and orofacial region is often not the primary source of the pain, making differential diagnosis extremely difficult. Referral of pain from one structure to seemingly another site is very common and is explained in part by the convergence of noxious input in the subnucleus caudalis.²⁸ Extracranial intraoral disorders and musculoskeletal cervical and temporomandibular disorders (TMD) will be discussed in more detail later in this chapter.

Pain in and around the eyes is relatively common, but seldom is it a result of noxious stimuli originating in the eye, extraocular muscles, or optic nerve. Rather, pain is commonly referred to the eye from other structures; however, pain referral to the face and mouth from the eye is uncommon. Pain perceived to be emanating from the ear is also very common. Although the source of the pathology may be from the ear (e.g. otitis externa and media, mastoiditis, eustachian tube disorders, neoplasia such as acoustic neuroma) (Fig. 54.1), again, the majority of ear pain is

Table 54.3 IHS 11 headache or facial pain attributed to extracranial disorders.

IHS 11.1	Headache attributed to disorders of cranial bones
IHS 11.2	Headache attributed to disorders of the neck
IHS 11.3	Headache attributed to disorders of the eyes
IHS 11.4	Headache attributed to disorders of the ears
IHS 11.5	Headache attributed to rhinosinusitis
IHS 11.6	Headache attributed to disorders of teeth, jaws, or related structures
IHS 11.7	Headache or facial pain attributed to TMD
IHS 11.8	Headache attributed to other extracranial structures

referred from another source. Pain in the nose and paranasal sinuses can arise from inflammation, infection, and malignant disease. The cause is primarily traction or distention of pain-sensitive structures leading to pain in the affected area. As with the above extracranial structures, the nose and sinuses commonly refer pain to adjacent structures, such as the teeth. Due to the broad sensory innervation of the throat, pain is referred to and from both adjacent and distant structures.

Intraoral pain disorders

Intraoral pain disorders include odontogenic pain, and pain conditions associated with mucogingival tissues, tongue, and salivary glands. Odontogenic pain is defined as pain associated with the teeth and periodontium. Tooth pain includes reversible and non-reversible pulpitis and pulpal necrosis. Teeth often refer pain to other teeth as well as to distant areas in the head, neck, and jaw. Pain conditions

associated with the supporting tissues of the teeth include acute apical periodontitis, acute apical abscess, and acute periodontal abscess. Mucogingival and glossal pain disorders may be localized or generalized throughout the mouth. The previously mentioned neuropathic burning mouth syndrome (BMS), also known as stomatodynia or oral dysesthesia, is characterized by burning mucosal, glossal, and/or palatal pain sometimes with associated taste sensations. Psychological disorders including anxiety and depression, systemic and localized disease, allergies, dietary deficiencies, hormonal changes, and xerostomia; all have been considered as possible etiologic possibilities. BMS is most prevalent in postmenopausal women. One concept is that chorda tympani hypofunction may play an important role in the pathology.²⁹

Localized pain conditions include acute necrotizing ulcerative gingivitis, recurrent aphthous stomatitis, herpes simplex candidiasis, and injury from trauma. Generalized pain conditions can result from physical, chemical, or drug-induced causes including chemotherapy, radiation therapy, dermatologic disorders, and systemic disease including pain secondary to HIV. Pain disorders associated with salivary disease or dysfunction can result from trauma, neoplasia, infection, e.g. mumps, inflammatory disorders such as acute suppurative and chronic recurrent sialadenitis and sialolithiasis, or salivary calculi or "stones".

Most intraoral pain disorders are familiar and routinely screened for by dental health professionals. However, atypical odontalgia, discussed above as a persistent neuropathic pain, is not familiar to general dentists. Even though the prevalence of atypical odontalgia is not known, studies suggest 3–5% of endodontically treated teeth may develop this persistent pain condition.^{30–32} Due to the lack of understanding of CNS pain mechanisms and the complexities of persistent pain syndromes, atypical odontalgia is a commonly mistreated diagnosis (Fig. 54.2). Imaging studies and clinical examination of the tissues appear normal with no obvious source of local pathology. However, the constant pain continues at the site for months and years.³³ The condition typically occurs subsequent to dental treatment and is thought to be peripherally and even centrally generated with possible alterations in the descending inhibitory pathways. This is consistent with the concept that non-responding persistent pain disorders, irrespective of their peripheral location, may be regulated centrally and have similar neuropsychologic impacts.³⁴ Also, there is some evidence that the sympathetic nervous system might also be involved in the maintenance of this continuous pain condition.³⁵

Atypical odontalgia is defined as a continuous, variable, diurnal tooth or tooth site pain of greater than 4 months' duration, with no obvious source of local pathology. It is often described as an aching, burning, and/or pressure sensation with a history of

Fig. 54.1 Acoustic neuroma can initially present as face and jaw pain.

Fig. 54.2 Panoramic radiograph revealing multiple unnecessary endodontic procedures for persistent neuropathic intraoral (atypical odontalgia) pain.

dental treatment, or trauma resulting in deafferentation of peripheral nociceptive nerve endings. The pain is located in a region where a tooth has been endodontically or surgically treated. Local provocation with temperature or loading and local diagnostic anesthetic injections are equivocal. Most atypical odontalgia patients have other comorbid pain conditions and higher scores for depression and somatization. Significantly lower scores on quality-of-life measures are also found.³⁶ Unfortunately, this diagnosis is often mistreated with repeated root canal therapies, apicoectomies, and even extractions. The result is worsening pain and irreversible harm to the patient. Treatment typically consists of tricyclic antidepressants, gabapentin and other membrane stabilizers, tramadol and topical lidocaine.

Musculoskeletal cervical and temporomandibular disorders

Musculoskeletal conditions affecting the jaw (TMD) and neck are the major cause of non-odontogenic pain in the orofacial region.³⁷ They include cervical spine and temporomandibular joint (articular) disorders; and cervical and masticatory muscle (non-articular) disorders. As with other musculoskeletal disorders, both neck and jaw symptoms wax and wane. Even though they are not life-threatening, they can significantly affect quality of life. They are defined as a collection of quite disparate musculoskeletal dis-

orders, articular or non-articular, that affect the neck and jaw, often with similar signs and symptoms.

Cervical spine disorders

Pain disorders associated with the cervical spine can involve the muscles, ligaments, facet joints, bones, discs, and neural tissues.³⁸ The traditional classification of these soft tissue and articular disorders includes diagnostic terms such as myositis, cervical sprain/strain, fibrositis, facet syndrome, osteoporosis, spondylosis, and osteoarthritis; articular hyp- and hypermobility; discogenic disease, and cervical nerve disorders. Eight percent of the US population seeks treatment for cervical spine disorders. Prevalence generally increases in frequency and intensity with age up to the fifth decade of life and is higher among women than men. A common traumatic cause of cervical symptoms is the damage that occurs during acceleration–deceleration (extension–flexion) injuries to the neck referred to as “whiplash” injuries.^{39,40} As with the various TMDs, the etiology of many of the cervical disorders is not well understood. Therefore, in the absence of fracture and disease, another classification has been proposed. It is modeled after the guidelines for low back pain and focuses on signs and symptoms to facilitate better communication among health professionals (Table 54.4).

Symptomatically, the cervical region overlaps with the craniofacial region, because the upper cervi-

Table 54.4 Cervical spine subclassification scheme.

Category 1	Neck symptoms without musculoskeletal and neurologic signs
Category 2	Neck symptoms without neurologic signs; musculoskeletal signs are present with a decrease in cervical range of motion and/or tension, plus pain on palpation of the cervical muscles
Category 3	Neck symptoms with musculoskeletal and neurologic signs that may include decreased or absent deep-tendon reflexes, weakness, and sensory deficits
Category 4	Radiation of symptoms or cephalic symptoms in addition to symptoms of category 1, 2, or 3; cephalic symptoms may include headaches, dizziness/unsteadiness, nausea/vomiting, tinnitus, visual problems, dysphagia, memory/cognitive problems, and reduced/painful jaw movements

cal nerves, discs, facet (zygapophyseal) joints, and muscles are potential sources of referred pain. The second and third cervical nerves innervate the angle of the jaw, the region inferior to the temporomandibular joint (TMJ), and parts of the ear, neck, and back of the head. Therefore, any irritation and/or dysfunction of these nerves can be associated with facial pain. As was discussed previously, convergence of input from the upper cervical nerves (C1, C2, and C3) with input from the trigeminal nerve in the trigeminocervical complex in the subnucleus caudalis in the brainstem can result in incorrect cortical discrimination of the actual source of the pain.⁴¹ Therefore, the patient may not be able to determine whether the source of the pain is in their neck, head, or jaw. Additionally, the upper cervical discs,⁴² as in discogenic disease; and facet joints,^{43–45} as in spondylosis and osteoarthritis, are other common sources of referred pain to the craniofacial region. Lastly, trigger points (tight bands) in cervical myofascial pain can be another

confusing source of referred pain to other cervical regions as well as the craniofacial region (Fig. 54.3).⁴⁶

Cervical findings are very prevalent in university-based orofacial pain centers. In a recent study at University of California San Francisco Center for Orofacial Pain, 86% of all patients seeking treatment had cervical findings and 42% had moderate to severe cervical muscle tenderness (Fig. 54.4).⁴⁷ It is the responsibility of the dentist to determine if the cervical findings are a primary source of the patient's orofacial pain complaint or a concomitant finding. A simple screening question can help with this differentiation. If chewing or other uses of the jaw do not change the patient's primary orofacial pain complaint, the dentist should be suspicious of a cervical spine disorder. The dentist should screen the cervical region for proper range of motion and soft tissue tenderness. If there is any significant mobility dysfunction or soft tissue tenderness, it needs to be investigated by a medical colleague with orthopedic training. Unfortunately in many cases, cervical diagnoses go undetected by the community dentist and patients are improperly treated.

Fig. 54.3 Noxious input from the upper cervical nerves (C2 and C3) converges with noxious input from the trigeminal nerve primarily in subnucleus caudalis that can result in incorrect cortical discrimination of the actual source of the pain.

Temporomandibular disorders

Temporomandibular disorders (TMD) were referred to as a syndrome in the past. Common terms were "TMJ", "TMJ syndrome", or "TMJ pain-dysfunction syndrome". Presently they are considered a collection of various distinct articular or muscular conditions affecting the jaw, many times with similar signs and symptoms, but different underlying mechanisms. The common clinical presentation is any combination of jaw, face, head, or ear pain, TMJ noises such as clicking, popping or crepitus, or grating, and/or limited jaw opening, jaw catching, and locking.⁴⁸ Related symptoms, without proven cause and effect, include global headaches, neck pain, tinnitus, ear fullness or perceived hearing loss, and dizziness. Pain in the TMJ region is reported in approximately 10% of the population over 18 years of age (8–15% for women and 3–10% for men).⁴⁹ Recent studies have shown that these reported symptoms and clinical signs rarely

Fig. 54.4 Cervical muscle tenderness in patients seeking treatment at a university-based orofacial pain center.

become progressively more severe or disabling; however TMD-related pain is the most common persistent orofacial pain with a prevalence of about 10–15% worldwide. Epidemiological studies reveal that females seek treatment more than males. The gender ratio varies between cross-sectional studies from anywhere from 4:1 to 2:1 female to male. The peak age is approximately 35–45 years (the child-bearing years of females).⁵⁰

Although the etiology of the various subsets of TMD was in the past thought to directly relate to occlusal discrepancies and improper jaw relationships, presently the number of related contributing factors for each specific diagnosis is uncertain and many times unknown. Recent systematic reviews of randomized controlled trials (RCTs) have concluded that malocclusion is not directly correlated to the various subsets of TMD.⁵¹ Contributing etiologic factors include trauma, possibly parafunction, gender and hormonal factors, systemic factors, overuse of the masticatory system, and psychosocial and behavioral factors.⁵² Recent evidence suggests a specific gene expression, primarily in females, implicated as a risk factor for persistent orofacial pain.⁵³ The number of comorbid conditions is substantial in many patients seeking treatment, especially when the orofacial pain condition has become persistent.⁵⁴

Classification of articular disorders

The American Academy of Orofacial Pain’s 2008 classification of TMD includes a disparate group of articular and non-articular conditions.⁵⁵ TMJ disorders include congenital, developmental, or acquired disorders, disc derangement disorders, condylar dislocation, inflammatory disorders, non-inflammatory disorders, ankylosis, and fracture of the condylar process (Table 54.5).

Table 54.5 Temporomandibular joint disorders (modified from the American Academy of Orofacial Pain’s classification).

Congenital, developmental disorders and acquired disorders
Disc derangement disorders:
Disc displacement with reduction
Disc displacement without reduction
Temporomandibular dislocation
Inflammatory disorders:
Synovitis and capsulitis
Polyarthritides
Osteoarthritis (non-inflammatory disorders):
Active
Stable
Ankylosis
Condylar fracture

Developmental and acquired disorders

Developmental disorders of the TMJ include: agenesis (lack of development), aplasia (faulty development), hypoplasia (incomplete or under-development of the condyle), and hyperplasia (non-neoplastic over-development of the condyles).^{56,57} Acquired disorders include benign (e.g. osteoma, chondromas, synovial chondromatosis),⁵⁸ malignant or metastatic neoplasms (e.g. squamous cell carcinomas, primary nasopharyngeal tumors).⁵⁹ Approximately 3% of malignant neoplasia metastasize to the mandible, usually to the body or ramus.⁶⁰

Disc derangements

Disc derangement disorders represent an abnormal anatomical relationship or misalignment of the articular disc and condyle. Recent studies are revealing, however, that there is a great deal of variation in the disc position even in individuals without joint pain, joint noise, or jaw dysfunction. Magnetic resonance imaging (MRI) studies of asymptomatic volunteers have revealed that about one third of these individuals had displaced discs.^{61,62} Most of the volunteers had a partial disc displacement that reduced on opening with a small number not reducing on opening.^{63,64} Stretched or torn collateral discal ligaments are thought to be the reason why discs become displaced, although there is still uncertainty regarding the natural history of these derangement conditions.⁶⁵ Articular discs are typically displaced anteriorly and medially, but can also be positioned laterally,⁶⁶ or even posteriorly.⁶⁷

Derangement disorders occur as disc displacement with reduction, disc displacement without reduction, and disc adhesion. The most common disc disorders are disc displacements with reduction. The reduction occurs when the condyle moves into a more normal position with an unstable disc during translation, usually creating a joint sound (i.e. clicking or popping) at the time of the improved relationship of the condyle with the disc. On closing, the condyle moves posterior of the disc resulting in a closing click. Jaw clicking occurs in 50–55% of the adult population, representing a relatively common biologic variation. Disc displacement can be either asymptomatic (non-painful) or symptomatic (painful) at the time of the click. When a momentary hesitation or locking (catching) occurs, analogous to a shoulder impingement, the displacement is referred to as a disc impingement disorder. Symptomatic disc displacement and impingement disorders require management.

Disc displacement without reduction (disc fails to re-establish an improved anatomical relationship) can either be acute (less than 3 months’ duration) or chronic (3 months’ or greater duration) (Fig. 54.5). The acute condition is often quite painful with marked

reduction in condylar translation; however, it can on occasion be painless. The chronic condition is usually less painful with a normal or near-normal range of condylar translation over time. In the chronic stage, as the tissues adapt, pain-free range of motion increases, but articular changes may be seen on imaging due to the change in force loading.^{68,69} Lastly, disc adhesion is a disc disorder created by the disc adhering to the temporal component of the fossa creating a static disc position and altered joint mechanics. With disc adhesion, the condyle translates under the posterior band of the disc causing a click and then continues to move beyond the anterior band of the disc resulting in a second click. During jaw closure, the clicking occurs at the same two places as it did during opening.⁷⁰

Condylar dislocation

Condylar dislocation or open lock is a hypermobility condition of the jaw.⁷¹ It occurs when the condyle inadvertently becomes positioned anterior and superior to the articular eminence, during jaw opening or protrusion, and is unable to return to a closed position. It can be caused by trauma, extended periods of mouth opening such as a long dental appointment, or can be a manifestation of joint hypermobility. This condition requires the condyle to be manually dis-

tracted below the crest of the articular eminence, so the condyle can freely return to a closed position in the fossa. It is called an open lock or dislocation if a health provider has to reduce the anteriorly positioned condyle. This same condition is referred to as subluxation when the patient is able to self-manipulate the jaw back to a closed position.

Inflammatory and non-inflammatory disorders

Inflammatory joint disorders can occur as an inflammation of the synovium (synovitis) and/or joint capsule (capsulitis). This may be the result of trauma, infection, or cartilage degeneration, or the sequelae of a systemic polyarthritic or collagen disease (rheumatoid arthritis, lupus, Reiter's syndrome).⁷² Inflammatory joint conditions typically present with localized joint pain that limits jaw movements. Non-inflammatory joint disorders include primary and secondary osteoarthritis. Osteoarthritis (OA) is defined as a non-inflammatory degenerative condition of the joint characterized by deterioration and abrasion of articular tissue and concomitant remodeling of the underlying subchondral bone due to overload of the remodeling mechanism.⁷³⁻⁷⁷ In susceptible individuals mechanical overload can involve the production or release of free radicals, cytokines, fatty acid catabolites, neuropeptides, and matrix-degrading enzymes, resulting in a degenerative disease state.⁷⁸

OA is classified as primary OA when the etiology is unknown and secondary OA when an etiologic event or factor can be identified (e.g. gout, Cushing's disease, osteonecrosis, infections, Charcot's neuropathic pain). It can be further categorized into active OA or stable OA, sometimes referred to as osteoarthritis. Active OA is related to an active change or degeneration in the articular tissues, whereas stable OA refers to the recortication of the articular osseous structure with a lack of any further structural change (Fig. 54.6).

Fig. 54.5 MRI sagittal view of an anterior disc displacement without reduction.

Fig. 54.6 (a) Active osteoarthritis is an active change or degeneration in the articular hard tissues. The cortical outline is no longer intact and there are erosions and subcondral bone cyst formation. (b) Stable osteoarthritis is a recortication (smooth surface) of the articular hard tissues and a probable end to any further structural change.

Ankylosis and fracture

Ankylosis is a hypomobility condition of the jaw when either fibrous or bony adhesions restrict condylar translation thus limiting jaw mobility and function (Fig. 54.7). Ankylosis is often the sequelae of trauma, including condylar fracture, infection, significant inflammation, or adhesions resulting from surgical intervention. The last articular diagnosis is fracture of the condyle. This condition usually results from direct trauma to the mandible. Fracture can be idiopathic or even iatrogenic, when secondary to another pathologic process. Ankylosis, condylar degeneration, or OA are possible sequelae.⁷⁹

Muscular disorders

The underlying mechanisms that cause masticatory muscle pain are similar to those that cause skeletal muscle disorders throughout the rest of the body. Some mechanisms thought to be related to muscle pain include overuse, localized ischemia, spontaneous activity of deep nociceptors, sympathetic nervous system hemodynamic perfusion changes, and changes in descending anti-nociceptive modulation.⁸⁰⁻⁸² Endogenous substances such as bradykinin, serotonin, prostaglandins, neuropeptides, substance P, and others are thought to sensitize the peripheral nociceptive nerve endings resulting in pain in the muscle.⁸³ Deep tissue inflammation can upregulate nociceptive behaviors which may not be effectively modulated by neuropeptide antagonists, resulting in more pain.⁸⁴

The concept that bruxism is a major cause of masticatory muscle pain is being questioned in that most subjects that brux do not have muscle tenderness.⁸⁵ Also, the historic dental view that masticatory muscle pain is related to occlusal interferences is no longer a

viable concept. Systemic conditions that can produce muscle pain include polymyalgia rheumatica, polymyositis, lupus erythematosus, and fibromyalgia. It is also important to distinguish between the cranial muscle tenderness associated with the various headache types and primary masticatory muscle tenderness, because even though the symptoms of these conditions can be very similar, the source of the pain is quite different, requiring very different management strategies.⁸⁶ Masticatory muscle disorders include local myalgia, myofascial pain, centrally mediated myalgia, myospasm or trismus, myositis and tendonitis, myofibrotic contracture, and neoplasia (Table 54.6).

Local myalgia

Local myalgia is characterized by localized or regional dull ache and stiffness in the masticatory muscles. There is typically little to no pain at rest. The pain increases with jaw function and often results in a decreased active jaw opening that increases with passive stretch. The patient often reports muscle weakness, fatigue, and increased pain when eating hard foods, yawning, and with prolonged opening. Local myalgia can include such conditions as protective muscle splinting as a result of TMJ pain, muscle fatigue, and delayed-onset muscle soreness. Delayed-onset muscle soreness or postexercise muscle soreness is a painful muscle condition related to intense or unaccustomed use of a muscle.⁸⁷ The overuse results in interstitial inflammation and a delayed pain in the muscles 8–24 hours later.

Myofascial pain

Myofascial pain is characterized by a regional or local dull, aching muscle pain that increases during function. Clinically there are localized tender sites or trigger points in the muscle, tendon, or fascia. Palpation of the trigger point provokes pain referral to a distant site such as the teeth, ear, or head and this must be present to meet the criteria for myofascial pain (Fig. 54.8).^{88,89} Patients may also report muscle stiffness, ear symptoms such as tinnitus, decreased mouth opening that can be passively stretched by more than 4 mm, and hyperalgesia in the region of the referred

Fig. 54.7 CT scan of bony ankylosis following temporomandibular surgery.

pain. Myofascial pain is not considered an inflammatory process; whereas tendonitis is an inflammation and/or soreness in the tendinous attachments of masticatory muscles.

Centrally mediated myalgia

Fibromyalgia, a type of general or global muscle pain involved with CNS upregulation, can be confused with local or regional muscle pain if the clinician is not comprehensive with the history taking and physical assessment process.⁹⁰ Fibromyalgia is characterized by a continuous, aching pain in many areas of the body. It is associated with generalized fatigue, chronic headache, irritable bowel syndrome, sleep disturbance, and emotional distress including anxiety, depression, and somatization. The American College of Rheumatology has developed a screening examination for fibromyalgia. They have identified 18 points (9 pairs) on the body that are normally non-painful with palpation. If 11 or more of these points are painful to palpation and there is pain in three out of four quadrants of the body for at least 3 months, this suggests a positive fibromyalgia screening.⁹¹ Patients suspected of fibromyalgia should be referred to rheumatology for further evaluation. Centrally mediated muscle pain is thought to be associated with the upregulation of central mechanisms. The pain may result from prolonged nociceptive input to the CNS resulting in antidromic effect on the afferent peripheral neurons. This can result in the release of pain-modulating substances such as bradykinin and substance P that cause pain. Chronic exposure to emotional stress and other sources of deep pain input, such as chronic upregulation in the autonomic nervous system, are thought to be possible underlying sources of the centrally mediated pain.

Fig. 54.8 Localized tender sites or trigger points in the muscle (red dot), tendon or fascia with referral to a distant site such as the teeth.

Myospasm

Myospasm or trismus is an acute muscle disorder characterized by a sudden, involuntary, tonic contraction (fasciculation) of a muscle. The acute pain is present at rest as well as during function, and function is significantly limited. The jaw cannot be manually stretched open beyond the patient's voluntary opening (hard end-feel) unlike local myalgia or myofascial pain. Myospasm involves the entire muscle and produces a dramatic increase in electromyography (EMG) activity in the muscle similar to maximum voluntary clench, again unlike the slight increase associated with myalgia or myofascial pain.⁹² Myospasm is a relatively rare muscle disorder of the masticatory muscles. One common cause of myospasm of the medial pterygoid is a mandibular nerve block. The risk of myospasm increases when the injection is repeated several times to achieve profound anesthesia. This inadvertently may cause local trauma, bleeding, or the introduction of intraoral organisms into the muscle resulting in myospasm.

Myositis and tendonitis

Myositis is defined as a true inflammation of muscle usually due to direct trauma and/or infection. Swelling, erythema, and increased temperature over the entire muscle are common. Continuous severe pain and diffuse tenderness result in increased pain with function resulting in significant limitation in the range of motion. Ossification of a muscle can occur secondary to inflammation which leads to myositis ossificans.⁹³ The inflammation may occur in the tendinous attachments of the muscle referred to as tendonitis or tendomyositis. When the tendinous attachments become inflamed, there is severe pain with use and palpation. This inflammatory condition often requires aggressive anti-inflammatory management.

Muscle contracture

Muscle contracture or myofibrotic contracture is a painless shortening of a muscle as a result of fibrosis or scarring of the supporting tendons, ligaments, or muscle fibers. Jaw opening is limited and usually not painful except when the muscle is extended beyond its functional length. When the opening is stretched there is an unyielding firmness or hard end-feel. This muscle disorder can occur following a long period of limited range of motion, such as with extended use of intermaxillary fixation.

Muscle neoplasia

Muscle neoplasia is defined as a new, abnormal, or uncontrolled malignant or benign growth of muscle tissue, and may or may not be associated with pain. The tumors can be present within the muscle or more

commonly are extensions from adjacent structures or metastases from remote sites. Swelling, trismus, paresthesias, and possibly pain are common features of these rare tumors. Confirmation with imaging and biopsy is required when a tumor is suspected.^{94,95}

Assessment of musculoskeletal disorders

Screening history and examination

The collection of baseline records and indicated diagnostic tests is fundamental to the proper management of jaw disorders. The extent to which any or all of the elements of evaluation are pursued depends on the magnitude of the presenting complaints and the potential for the problem to progress physically and psychologically. Screening for jaw disorders is an essential part of all routine dental and orofacial pain examinations.⁹⁶ Basic assessment of all patients should also include behavioral and psychosocial screening by the dentist during the history-taking process. The history should include questions to evaluate behavioral, social, emotional, and cognitive factors which may initiate, sustain, or result from the patient's condition. If significant findings are identified and recorded, a comprehensive history and examination should be conducted.⁹⁷ Appropriate imaging studies of the jaw and craniofacial structure, as well as other diagnostic tests including blood and urine chemical analyses are important diagnostic tools in specific cases. Also, diagnostic somatic and sympathetic nerve blocks, intra-articular TMJ injections, and trigger point injections are extremely valuable as diagnostic aids.

Comprehensive history and examination

The gold standard for diagnosis of TMD is still the interpretation of findings from a comprehensive history and comprehensive physical examination.^{98,99} The comprehensive history parallels the traditional medical history and review of systems, and consists of the chief complaint(s), history of the complaints, medical history, dental history, and personal history (social and family). It is important for the dentist to not get lost in multiple complaints.

The complaints should be rank ordered beginning with the chief complaint by the patient. The history should include a chronological history for each complaint. The comprehensive physical examination consists of a general inspection of the head and neck, including: a visual inspection and palpation; cursory evaluation of the cranial nerves; a comprehensive orthopedic evaluation of the TMJ and cursory evaluation of the cervical spine; a masticatory and cervical muscle evaluation; and an intraoral evaluation.

Behavioral and psychosocial assessment

With pain being defined at the beginning of this chapter as an unpleasant sensory and *emotional* experience associated with actual or potential tissue damage or described in terms of such damage, it is readily apparent that a biopsychosocial model is required to manage orofacial pain. This assessment becomes especially important when these pain conditions become persistent. It has long been established that persistent pain disorders result in a number of biologic and psychologic changes. Persistent pain patients exhibit significant anxiety, depression, somatization, high utilization of health services, and frequent use of pain medications.¹⁰⁰ Because patients develop maladaptive patterns that prolong suffering and prevent effective symptom management, the comprehensive history needs to include an evaluation of the behavioral, social, emotional, and cognitive factors that either can sustain or result from their pain complaints.

Psychological and psychosocial assessment can be effectively incorporated as part of the pain history with standardized self-report questionnaires. A dual-axis system for physical and psychological assessment for TMD referred to as the Research Diagnostic Criteria for TMD (RDC) was developed by an international team of clinicians–researchers in 1992.¹⁰¹ In 2005 they established a website with Axis I physical diagnoses, viable for research diagnostic classification standardization, and Axis II for psychological assessment.¹⁰² The psychological assessment measures include a visual analog pain scale, mandibular function questionnaire, depression and somatization system checklists, and a psychosocial functions graded chronic pain scale.

Self-report questionnaires are numerous and can include the Holmes and Rahe Scale for life changes,¹⁰³ the Interactive Microcomputer Patient Assessment Tool for Health (IMPATH),¹⁰⁴ and the TMJ Scale¹⁰⁵ as screening devices. These tests may indicate the need for a more extensive evaluation from a psychologist or psychiatrist. They may consider the need for other psychological inventories such as the Symptom Checklist-90-Revised (SCL-90-R), Post-traumatic Stress Disorder (PTSD) Civilian Checklist, Minnesota Multiphasic Personality Inventory (MMPI), Hamilton Depression Scale, West-Haven-Yale Multidimensional Pain Inventory, McGill Pain Questionnaire, and the Million Behavioral Questionnaire.^{106,107}

Imaging

Imaging of the TMJ and orofacial structures may be necessary to rule out structural disorders of the jaw and other medical conditions that may be masquerading as a jaw disorder.¹⁰⁸ Imaging should primarily be ordered after a comprehensive examination suggests some form of joint pathology or when there is a

suspicion of some other serious non-musculoskeletal pathology such as an infection or tumor. Corrected tomography has been the choice of imaging for hard tissue pathology in the TMJ.¹⁰⁹ Cone-beam computed tomography (CBCT) is the most accurate method for radiographically examining patients with suspected TMJ degenerative disease or other osseous pathology and structural aberrations (Fig. 54.9).¹¹⁰

MRI has diverse capabilities for the examination of suspected TMJ soft tissue disorders and pathology, i.e. disc displacement, effusion, and tumors. As the resolution improves and technical advancement occurs, MRI is clearly becoming the study of choice for complex problem solving. MRI studies on autopsy series of oblique sagittal and coronal views has been found to be approximately 95% accurate in determining disc position.¹¹¹ For the study of routine jaw disorders, MRI is rarely indicated for non-surgical TMD management, because the study does not usually change the treatment approach. However, if surgical intervention is a consideration, a MRI study can be a critical diagnostic aid for surgical treatment planning.

Additional diagnostic tests

A variety of additional diagnostic studies are available for use in select cases to assist in confirming a physical diagnosis. Diagnostic tests may include laboratory tests (blood chemistries) for systemic arthritides; neural blockade, somatic, and sympathetic nerve blocks; diagnostic specific injections of TMJ and trigger point injections of the cervical and masticatory muscle; and spray and stretch to determine if a soft-tissue trigger point is a source of pain. A physical

therapy evaluation is helpful to determine the appropriateness of a specific rehabilitation program, to evaluate the cervical spine as a source of orofacial pain, and to perform a fibromyalgia screening examination to determine the scope of the pain presentation (Fig. 54.10).

Fig. 54.10 Palpation of the lateral epicondyle region by a physical therapist as part of the fibromyalgia screening.

Adjunctive diagnostic devices

There are a number of electronic devices marketed to diagnose jaw disorders (TMD) including electromyography testing, jaw tracking, thermography, sonography, and vibration analysis. However, peer-reviewed articles have questioned the sensitivity (percentage of correctly diagnosed patients) and reliability (percentage of correctly diagnosed normals) of these technical diagnostic TMD tests. There is insufficient evidence that vibration analysis of the TMJ can diagnosis disc displacement with reduction any more accurately than the use of the stethoscope and palpation.¹¹² Many of the devices lack research support and are subject to great biologic variability.^{113–116} The risk of an incorrect diagnosis often based on over-interpretation of insignificant or normative physiological data can result in mistreatment or over-treatment of the patient. Jaw tracking instrumentation, that provides additional measurement data regarding mandibular movements, does not justify treatment of the occlusion for TMD patients. The “high-tech electronic devices” that record jaw relationships and jaw movement are often recording biologic variations that can be misleading. The interpretation that these data are supportive evidence that the occlusion needs to be altered from a TMD management standpoint is not in agreement with evidenced-based research. Jaw tracking can have technical benefit for the dentist that wants to use a semi-adjustable or fully adjustable articulator when comprehensive restorative, prosthodontic or implant dentistry is being contemplated for dental treatment.

The US Food and Drug Administration (FDA) and the American Dental Association (ADA) used the term “adjunctive diagnostic devices” when they approved jaw-tracking, EMG, and sonography devices *only* for the measurement of clinical jaw signs.¹¹⁷ Both organizations did not approve the devices for having the ability to make a diagnosis,^{118,119} with the ADA stating “... the interpretation of the test results rests with the dentist”. Also, the literature to date on the use of thermography for the diagnosis of orofacial pain has revealed conflicting evidence.¹²⁰ The primary concern with using these adjunctive devices is their low degree of diagnostic specificity, resulting in a high number of false-positive diagnoses and unnecessary treatment.¹²¹

Dental casts

As mentioned above, due to the many variables involved, it has been difficult to establish significant cause and effect correlations between the occlusion and TMD.¹²² Based on the literature, treatment involving the occlusion is rarely appropriate for specifically treating TMD. Therefore, because TMD is not directly correlated to the occlusion or specific jaw relationship, diagnostic casts to study the occlusion have little value in the assessment of TMD. However, casts can

be an important assessment aid for identifying wear patterns from sleep and awake bruxism and longitudinal comparisons of jaw relationship and/or occlusion changes secondary to an articular or muscular TMD condition. Also, they are extremely beneficial during the treatment planning process for complex restorative, prosthodontic, and orthodontic including orthognathic surgery cases. Cast surgery on mounted diagnostic casts prior to surgery is helpful for both the surgeon and the orthodontist.

Management of musculoskeletal disorders

The majority of patients with jaw disorders achieve good symptomatic relief with a medical model using non-invasive management.¹²³ Long-term follow-up studies show that 85% to more than 90% of patients have few or no symptoms after conservative treatment.¹²⁴ A recent meta-analysis of TMD treatment need reports an approximate 16% need for adults.¹²⁵ Jaw disorders are similar to other musculoskeletal disorders, but currently not enough is known about the natural course of most jaw disorders and which signs and symptoms will progress to more serious conditions. As in other musculoskeletal conditions, the TMD signs and symptoms vary and may be transient and self-limiting, resolving without serious long-term effects. Recent reports on the course of untreated disc displacement without reduction suggest that a natural resolution of symptoms occurs over time. The research from Boering and co-workers also suggests a natural course for not only some disc disorders but OA, as well. The peer-reviewed literature strongly supports that a special effort should be made to avoid aggressive, irreversible therapy for articular and non-articular jaw disorders.^{126,127}

As previously mentioned, treatment of the occlusion is rarely appropriate for specifically treating the subsets of TMD, based on the recent systematic reviews of RCTs.¹²⁸ There are many testimonials and belief systems that claim that occlusion or incorrect jaw relationship is the primary etiologic factor for TMD, but scientifically a direct correlation is largely unproven.^{129–133} Thus, based on the efficacy of the non-invasive medical model for the treatment of TMD and the lack of evidence that occlusal therapy is necessary, the old concept of phase I and phase II treatment is obsolete. As a patient’s TMD signs and symptoms improve with the conservative medical management model described in this chapter (“phase I treatment”), there is no scientific evidence to support the need for subsequent definitive treatment of the occlusion (“phase II treatment”).^{134–136} When TMD signs and symptoms resolve, the only compelling reasons to proceed with treatment of the occlusion would be based on dental (tooth and/or periodontal) pathology, mobility, discomfort, or esthetic reasons. And even then, great care should be

taken with this “at-risk” patient relative to minimizing trauma to the patient’s jaw including minimal appointments, limited jaw opening, and reduced force loading. Less rather than more complex dental procedures should be contemplated, especially when considering making changes in the occlusion.

A multidisciplinary medical model that includes patient education and self-care, cognitive behavioral intervention, pharmacologic therapy, physical rehabilitation, and/or orthopedic appliance therapy is endorsed for the management of nearly all patients (Table 54.7).¹³⁷ The management goals should be diagnosis specific. The common goals are reduction of pain, reduction of adverse loading, improvement of mobility and function, and restoration of activities of daily living. The emphasis should be on conservative therapy that facilitates the musculoskeletal system’s natural healing capacity. The management requires the patient to assume responsibility for the physical and behavioral management of his or her own problem. There is a small number of TMJ disorders that require surgical intervention, e.g. developmental conditions resulting in significant structural, functional and/or esthetic problems, tumors, ankylosis or fracture, that are discussed elsewhere in this textbook.^{138,139}

Patient education and self-care

The success of a self-care program depends on patient motivation, cooperation, and adherence. A successful program begins with a thorough explanation of the patient’s diagnosis or diagnoses and a discussion about the patient’s prognosis. Once the patient understands their condition, the self-care program is more meaningful and patient adherence is higher. When the jaw disorder is mild, patient education and instruction in a self-care program may be all that is required.^{140,141} The self-care instructions should be specific for the patient’s diagnosis and clinical presentation; and should be directed toward achievable goals. These instructions typically include resting the masticatory system through correct relaxed jaw posture awareness with an emphasis on not contacting opposing teeth unless swallowing, i.e. preventing awake clenching and grinding of the teeth. Patients need to be mindful of any other oral habits that may be delaying their recovery such as jaw protrusion, cheek sucking, or tongue bracing behaviors. Patients generally benefit from a soft diet and slower mastication. If they need joint protection, as in the case of joint inflammation or disc instability, patients benefit

from chewing on the affected side, limiting incising their food and avoiding prolonged opening.¹⁴² The instructions may also include palliative recommendations such as moist heat to increase circulation and relax muscles for local myalgia and myofascial pain. On the other hand, ice is the preferable thermal modality to decrease pain and inflammation when there is an acute joint inflammation. Self-massage of the affected muscles is another method to relax tight muscles and improve local circulation. Sometimes gentle range-of-motion exercises are appropriate to lubricate the joint, reducing joint pain and increasing range of motion. Other instructions may focus on head and neck posture, ergonomics and sleep positioning, and include general suggestions for improved health habits, cardiovascular exercise, and sleep hygiene.

Cognitive behavioral intervention

Behavioral intervention is an important part of the overall medical management program for patients with jaw disorders.¹⁴³ Simply making patients aware of their jaw habits is often enough to improve jaw relaxation skills, but changing persistent habits may require a structured program with a clinician trained in behavior modification strategies. Comprehensive stress management and counseling programs using a combination of EMG biofeedback, progressive relaxation, diaphragmatic breathing, and self-directed changes in lifestyle appear to be more effective than any one behavioral treatment procedure in isolation. Unfortunately, biofeedback is not generally effective for treatment of sleep bruxism.¹⁴⁴ Patients with persistent pain or who have experienced multiple treatment failures typically require in-depth psychological evaluation and treatment by a mental health professional such as a psychologist or psychiatrist.

Pharmacologic therapy

The indicated classes of pharmacologic agents include analgesics, non-steroidal anti-inflammatory agents, corticosteroids, anxiolytics, muscle relaxants, low-dose (pain-dosing) antidepressants, and nerve membrane stabilizers. The non-opiate analgesics, such as acetaminophen, are effective for mild to moderate pain, whereas the opioid narcotics, such as codeine, ultram, hydrocodone, and demerol, should only be used short term for controlling more severe acute pain.¹⁴⁵ Opioid narcotics produce tolerance and dependence and should be used on a time-contingent basis.¹⁴⁶ Non-steroidal anti-inflammatory drugs (NSAIDs), such as ibuprofen, naproxen, or nabumetone, are effective analgesics and anti-inflammatory agents. They are prescribed for painful articular inflammatory disorders, not usually for muscle disorders. They must be prescribed at therapeutic levels over a significant period of time to achieve the desired anti-inflammatory effects. Caution should be exer-

Table 54.7 Multidisciplinary management model.

Patient education and self-care
Cognitive behavioral interventions
Pharmacologic therapy
Physical rehabilitation
Orthopedic appliance therapy

cised when prescribing these medications, as they can cause gastrointestinal irritation and bleeding. When NSAIDs are contraindicated or ineffective, corticosteroids can be considered for persistent localized moderate to severe joint inflammation. These medications can be delivered orally, e.g. with a methylprednisolone dosepak or they can be injected directly into the temporomandibular joint, e.g. prednisolone.

The benzodiazepines, such as alprazolam, lorazepam, and diazepam, are most commonly prescribed for their anti-anxiety effects. These drugs act as depressants when used long-term; thus they should only be used short-term for acute muscle pain/spasm (trismus), to relax patients prior to jaw manipulation for acute disc displacement without reduction, or for sleep disturbances associated with anxiety.^{147,148} Muscle relaxants, such as cyclobenzaprine, metaxalone, and tizanidine, are useful for acute and/or chronic muscle pain. Cyclobenzaprine, which is quite similar chemically to the tricyclic antidepressants, is one of the drugs of choice by rheumatologists and pain specialists for generalized persistent muscle pain.^{149,150} Cyclobenzaprine (5–10mg at bedtime) is reported to also improve sleep architecture and reduce sleep bruxism. Tricyclic antidepressants such as nortriptyline, doxepin, and desipramine, when used in low dosages (10–75mg) have been shown to act on the CNS neurotransmitters, improving the patient's pain regulation. They are prescribed for persistent pain patients who have neuropathic pain, persistent myofascial pain, and poor restorative sleep.^{151,152} Studies suggest that they may also reduce sleep bruxism. Membrane stabilizers or anti-seizure drugs, such as carbamazepine and phenytoin, have been replaced with improved medications like gabapentin and pregabalin for persistent pain conditions including neuropathic atypical odontalgia pain. These second-generation medications have less significant side-effect profiles than the former drugs.¹⁵³

Physical therapy

Physical therapy is recognized as an effective, conservative approach for patients with jaw disorders.¹⁵⁴ A physical therapy consultation should be performed by a physical therapist and involves a comprehensive head, neck, upper quarter orthopedic evaluation, and fibromyalgia screening. Based on these findings, a rehabilitation program is designed to restore optimal masticatory, cervical, and upper quarter function as appropriate. The rehabilitation strategies are based on the patient's diagnoses, clinical findings, and the patient's personal treatment goals. Treatment goals commonly include pain control, optimizing joint biomechanics and range of motion, restoring functional muscle strength and endurance, and restoring the ability to perform activities of daily living of the jaw, such as talking, chewing, yawning, and singing; or of the cervical and upper quarter regions such as sitting, reading, driving, lifting, and reaching.

The management begins with patient education and instructions in a structured self-care program. The next goal is to reduce pain as efficiently as possible, so the patient can begin exercising their jaw, neck, and upper quarter as appropriate. Physical agents such as moist heat, cold packs, transcutaneous electrical nerve stimulators (TENS), iontophoresis, ultrasound, and vapocoolants may be used initially for pain control. Moist heat increases local circulation and relaxes muscles. This improves the nutrition to the tissue and removes the inflammatory by-products from the area. Cold packs anesthetize the area reducing pain, and they initially decrease the circulation reducing an inflammatory response. TENS inhibits "c" fibers, thereby reducing the propagation of pain. Iontophoresis uses an electric galvanic stimulator to deliver corticosteroids through the tissues. Ultrasound is a thermal device that produces sound waves. The sound waves penetrate the skin to a depth of up to 5cm vibrating the tissue and creating a mechanical heat that results in increased local circulation and muscle relaxation (Fig. 54.11). Vapocoolants anesthetize the skin, so that a muscle with tight bands (trigger points) can be stretched, deactivating the referred pain from the trigger points (Fig. 54.12).

Fig. 54.11 Ultrasound application to the right masseter region.

Fig. 54.12 Spray and stretch technique to eliminate a masseter muscle trigger point that is referring pain to the head and teeth.

Soft-tissue mobilization and myofascial release techniques are commonly used to increase local circulation, restore normal muscle tone, and deactivate myofascial trigger points (Fig. 54.13). Once the patient has better pain control, the therapist can mobilize the joints as needed, and begin a range-of-motion and muscle conditioning program. Joint mobilization is essential for the acute disc displacement without reduction. The therapist manually distracts and translates the condyle under the posterior band of the displaced disc, restoring full condylar translation and the former condition of disc displacement with reduction. Joint mobilization is also indicated when jaw mobility is limited for other reasons. Mobilization techniques to restore rotation and translation for optimal joint biomechanics are performed before muscle stretching is initiated. This same philosophy is applied to other joints of the upper quarter. Once improved joint mechanics are achieved, range-of-motion and stretching exercises are introduced to facilitate normal movement of the joint and muscles. Lastly, muscle strengthening and conditioning ensure the safe return to previous levels of function without reinjury. Patients that only do palliative treatments are likely to reaggravate their tissues when they advance their diet, attempt to use their jaw normally, or resume other activities of daily living.

Physical therapy for persistent pain conditions requires less peripheral (local) management and involves strategies to influence the CNS. The therapist must address sleep positioning and sleep hygiene to enhance restorative sleep. It is also essential to motivate patients to be more active, establishing realistic and achievable exercise goals to improve general strength and endurance. Education about diaphragmatic breathing and relaxation training is another important component in the rehabilitation program; and lastly, stressing the importance of proper pacing of their activities, so as not to overdo it when a patient is having a better day, leading to relapse and increased pain the following day. Better restorative sleep, increased activity, improved relaxation skills, and improved pacing with activities of daily living improve the patient's central pain modulation system.

Fig. 54.13 Soft tissue mobilization of the left masseter.

Throughout physical therapy, the patient should be frequently reassessed by the physical therapist and the referring clinician. The patient should be achieving their management goals and requiring less and less treatment with the therapist. If the patient is not improving as expected, additional diagnostic testing and/or consultations must be considered. Ultimately, the patient should be discharged from treatment with an independent home management program.

Orthopedic appliance therapy

Orthopedic appliances, also referred to as orthoses, occlusal splints, bite splints, bite plates, night guards, or bruxism appliances, have been commonly used in the management of jaw disorders.¹⁵⁵ There is general agreement that some patients with myofascial pain, articular disc instability, and joint inflammation sustain their symptoms when they brux their teeth at night. These patients may benefit from appliances worn during sleep. Also, appliances have dental benefits with regard to protecting the teeth and/or restorations from wear and fracture, as well as decreasing tooth sensitivity and mobility. Appliances should only be worn during sleep in order to limit the amount of time the appliance masks the periodontal proprioceptive input that allows the patient to return to their intercuspal position when the appliance is removed. Eventually random wear at night, during periods of increased stress, should be all that is necessary.

There still is great debate about how to design an appliance for the greatest efficacy.¹⁵⁶ Systematic reviews of RCTs suggest that appliance design, i.e. specific types of occlusal interfaces and/or jaw positions, are not a very critical factor for the management of bruxism or masticatory muscle pain. Most dentists agree, however, that orthopedic appliances should cover all the teeth on either the maxillary or mandibular arch in order to prevent irreversible changes in the occlusion (Fig. 54.14). Partial coverage appliances can allow teeth to extrude or intrude and/or cause condyles to reposition themselves within the articular fossae. The type of material, hard acrylic or soft vinyl, also is no longer an important consideration. The efficacy of soft vinyl appliances, which were questioned in the past, has been reported to be comparable to that of hard acrylic appliances in recent studies.¹⁵⁷

Currently an appliance called the Nociceptive Trigeminal Inhibition (NTI) splint is being widely marketed to the dental profession and the public (Fig. 54.15). The appliance covers the maxillary central incisors allowing contact on jaw closure with only the lower incisors based on the old concept of the Lucia Jig and the Leaf Gauge by Long.^{158,159} The anterior contact reportedly decreases jaw elevator muscle (EMG) activity and associated muscle pain and headache. However, a recent study reported that the decrease in postural EMG activity in a myofascial group was short-lasting, and thus should not be

Fig. 54.14 (a, b) Frontal and occlusal views of a maxillary orthosis.

considered as evidence that the appliance has a long-term muscle relaxation effect.¹⁶⁰ Anterior tooth contact only increases TMJ loading, possibly resulting in an exacerbation of an articular condition, e.g. inflammation or OA of the TMJ. Studies have revealed no significant differences in muscle pain between a full-coverage stabilization appliance or an NTI appliance after 3 months.¹⁶¹ At 6-month follow-up, the stabilization splint was favored over the NTI splint by a number of the patients with the added advantage of less risk for occlusal changes.¹⁶²

In summary, recent scientific reviews and RCTs find no difference in efficacy between active full-occlusal coverage appliances versus palatal coverage placebo appliances for the treatment of bruxism.¹⁶³ They also have found that full occlusal coverage stabilization appliances performed no better than active, non-occluding palatal coverage appliances for the treatment of masticatory muscle pain.^{164–166} The effectiveness of occlusal appliance therapy versus conservative treatment for masticatory muscle pain as suggested in this chapter is comparable in recent studies. One systematic review concluded that there was insufficient evidence to suggest that stabilization appliances are any more effective than other treatments, such as self-care, acupuncture, biofeedback,

relaxation, and exercises, for treatment of TMD pain.¹⁶⁷

Conclusion

Managing pain and relieving suffering should be at the core of the health professional's commitment to patients. Proper pain management is mandated in order to prevent the consequences of unrelieved pain. Recent scientific and clinical advances have recognized that unrelieved pain can cause delayed healing, an altered immune system, an altered stress response, vegetative symptoms, and permanent alterations in the peripheral and central nervous systems, resulting in persistent pain syndromes. Therefore, there is every medical and ethical reason to treat pain, including orofacial pain, in a timely manner with every resource available. In doing so, we need to provide irreversible, non-invasive treatment, when at all possible, that facilitates the natural healing process and that also helps to sufficiently alleviate pain. As health providers, we must always remember the axiom – physician, do no harm!

Chapter 55

Arthroscopy and Arthroscopic Surgery

Anders Holmlund

Arthroscopy provides unique possibilities for simultaneous intra-articular diagnosis and surgical treatment. This chapter describes the method for diagnostic arthroscopy and gives examples of the different pathological changes that may be observed in the temporomandibular joint (TMJ) during arthroscopy. Several surgical procedures, such as lysis and lavage, disc suturing, synovectomy, and restriction procedures, are described and critically reviewed, as are the postoperative course and sequela.

Development of temporomandibular joint arthroscopy

Modern arthroscopy started with the commercial introduction of the flexible fiber-light cable in the beginning of the 1970s. Another invention, the Hopkins rod-lens telescope, also introduced commercially in the 1970s, constituted a significant improvement in the optics. The first report on temporomandibular joint (TMJ) arthroscopy was published in the *Journal of Japanese Stomatology* in 1975 by Dr Masatoshi Ohnishi, who followed the strong Japanese tradition in the field of arthroscopy.¹ In 1980, Dr Ohnishi presented his experiences with TMJ arthroscopy in English.² Other reports followed, such as those of Dr Murakami in Japan, Dr Holmlund in Sweden, and Drs McCain, Kaminishi, and Sanders in the USA. TMJ arthroscopy now has a solid position as an important aid for both diagnosis and treatment in the field of TMJ surgery.

Anatomic considerations

The functional anatomy of the TMJ is beyond the scope of this chapter. However, there are some special considerations with regard to the arthroscopic procedure which should be mentioned. The joint is divided by the disc into an upper and a lower compartment. The volume of the upper compartment is about twice as large as that of the lower compartment. The kinetics of the TMJ is a combination of rotation and sliding movements where the disc-condyle complex slides down the eminence. In most disorders of the TMJ, this sliding movement is impaired. If translation is completely impaired, as in ankylosis, the joint space is almost totally closed, making safe puncture of the joint impossible. Fortunately, in most patients this is not so and the space is large enough to permit safe puncture of the joint. In the lateral and medial areas, the capsule and disc attachment become fused and attached to the lateral and medial poles of the condyle. Puncture of the upper compartment involves

only trocar penetration of the lateral capsule, while puncture of the lower compartment involves penetration of both the capsule and the disc ligament. Thus, puncture of the lower compartment always involves the slight risk of damaging the lateral disc attachment, which may, in turn, cause displacement of the disc medially. The TMJ capsule is thin in the anterior and anteromedial parts. This must be considered while distending the joint. If irrigation is performed with too much pressure, rupture of the anterior and medial capsule may occur, with subsequent extravasation of fluid into the surrounding tissues. The lateral capsule is better developed and is usually felt as resistant by the trocar when puncturing the joint.

Occasionally, the roof of the glenoid fossa is paper thin. In the author's experience with TMJ arthroscopy over a period of 25 years, accidental penetration into the middle cranial fossa should be almost impossible if the proper technique and instruments are used.

The TMJ is surrounded by important anatomic structures, i.e. the temporal vein and artery, the anterior wall of the acoustic meatus, and the tympanic membrane posteriorly, and the facial nerve inferiorly and anteriorly on the lateral side. The chorda tympani may run close to the medial capsule and the maxillary artery is located somewhat inferior to the joint on the medial side. Puncture of the TMJ must be planned with great care in order to avoid damaging these structures. However, it is relatively safe to insert the instruments from the lateral side between the temporal vessels posteriorly and the temporal branch of the facial nerve anteriorly.

Diagnostic arthroscopy

A careful case history and clinical examination are of great importance in TMJ diagnosis and arthroscopy since other supplementary techniques can never act as a substitute for a thorough clinical examination. Moreover, supplementary techniques (radiography, computed tomography (CT), magnetic resonance imaging (MRI), or arthroscopy) are all more invasive or costly. Such methods should therefore be regarded as important adjuncts to the clinical examination and can confirm or refute a tentative diagnosis. Whether arthroscopy should be chosen is more a question of what MRI or CT cannot achieve. One definite advantage of arthroscopy is that diagnosis and therapy can be performed simultaneously.

The indications are as follows:

- disc derangements;
- osteoarthritis;
- rheumatic joint disease;
- crystal-induced arthritis;
- synovial pseudotumors.

Two clinical variants of disc derangement exist: reciprocal clicking and chronic closed lock. In reciprocal

clicking, arthroscopic examination can sometimes confirm the clicking but it usually cannot because irrigation reduces friction. The arthroscope does not permit complete closing of the mouth and therefore any displacement of the disc cannot be determined. The arthroscopic anatomy is generally normal. A slight inflammation is usually present. Therefore, the value of diagnostic arthroscopy in patients with reciprocal clicking is limited to the assessment of the degree of synovitis.

In chronic closed lock, on the other hand, a degenerative process typically develops in the posterior part of the disc and the posterior disc attachment. Arthroscopically, there is a loss of the well defined boundary between the disc and the posterior disc attachment, with softening and hyperemia of the disc. In the closed position the disc remains in the anterior recess. Synovitis is present in most cases and in about 20% of cases the inflammation is more severe with presence of synovial hyperplasia.³ Arthrotic changes of the fibrocartilage and disc frequently occur.

Regarding osteoarthritis, the late stage of the disease correlates well with clinical signs (crepitation)⁴ and radiographic features (sclerosis, flattening, erosions).⁵ However, arthroscopy more accurately reveals the severity of cartilage and disc involvement and of the associated inflammation (Fig. 55.1).⁵ This information is important for choosing intra-articular pharmacotherapy, e.g. the use of steroids.

The TMJ may also be involved in rheumatic joint disease, e.g. rheumatoid arthritis, psoriatic arthritis, and ankylosing spondylitis. An early diagnosis of TMJ involvement is important. However, clinical signs and symptoms are non-specific and proposed radiographic features (erosions) are also found in joints with osteoarthritis and are demonstrated rather late in the disease process. Arthroscopy provides reliable information as to the degree of inflammation and cartilage involvement.^{6,7} In the chronic stage, adhesions seem to be a particularly important diagnostic marker.⁷

In rarer conditions, such as crystal-induced arthritis (gout, pseudogout), pigmented villonodular synovitis, and synovial chondromatosis, arthroscopy may be the only way to make a correct diagnosis. Gout and chondrocalcinosis show typical urate crystals and deposition of calcium salts respectively. In patients with pigmented villonodular synovitis, typical synovial hyperplasia with brown pigmentation is found. In patients with synovial chondromatosis, numerous loose cartilage bodies can be visualized almost blocking the joint space. These loose bodies are not always detectable with CT and MRI.⁸

Contraindications

Absolute contraindications include:

- bony ankylosis;
- advanced resorption of the glenoid fossa;

Fig. 55.1 Arthroscopic features of inflammation, osteoarthritis, and adhesions. (a) Right joint, upper compartment: increased vascularity in the posterior disc attachment. (b) Left joint, upper compartment: capillary hyperemia in the posterior disc attachment. (c) Left joint, upper compartment: synovial hyperplasia and capillary hyperemia in the posterior disc attachment. (d) Left joint, upper compartment: fibrillation in the temporal fibrocartilage, disc unaffected below. (e) Right joint, upper compartment: lesion in the temporal fibrocartilage, disc unaffected below. (f) Left joint, upper compartment: small disc perforation in posterior part of the disc. (g) Left joint, upper compartment: single fibrotic band (adhesion) between temporal fibrocartilage and disc in the medial part.

- infection in the joint area;
- malignant tumors.

Relative contraindications include:

- patients at increased risk for hemorrhage;
- patients at increased risk for infection;
- fibrous ankylosis.

Bony ankylosis is, for obvious reasons, a contraindication. In TMJs where the CT scan indicates advanced resorption of the glenoid fossa, diagnostic arthroscopy should be avoided because of the risk of accidental perforation into the middle cranial fossa.

In patients with an infection in the soft tissues surrounding the joint, diagnostic arthroscopy should be avoided, since there is a considerable risk of spreading an extra-articular infection into the joint. However, in the case of infectious arthritis, it may be desirable to perform arthroscopic puncture of the joint to establish drainage and irrigate the joint.

In cases of suspected malignant tumors, diagnostic arthroscopy should be avoided, since there is always a risk of spreading malignant cells with the irrigation fluid.

Patients at increased risk of bleeding should be carefully evaluated and prepared before arthroscopy in order to prevent this complication which may lead to hemarthrosis. Patients at increased risk of infection, e.g. immunodeficient patients, must also be carefully assessed especially as regards the need for prophylactic antibiotic therapy.

Arthroscopy equipment

Several publications have described the basic equipment for diagnostic TMJ arthroscopy.^{9,10} Fig. 55.2 shows a suitable set of instruments. Most telescopes have a diameter of about 2mm but ultrathin telescopes have recently been developed with a diameter of about 0.7mm. Such a reduction in diameter results

Fig. 55.2 Arthroscopic equipment. (a) Telescope, arthroscopic sheath, trocars, biopsy forceps, irrigation syringe, and light cable. (b) Camera and light source. (c) Arthroscopy in action.

in a loss of optical quality. There is also an increased risk that the instrument will break. However, more important than the diameter, is the quality of the optical system. A rod lens telescope has proved superior to other models. The telescope should have a direction of view of 30° . The field of vision is thereby much increased simply by rotating the instrument.

The arthroscopic sheath should fit properly on the telescope so that it just overlaps the telescope at the tip, thereby protecting the lens. The sharp and blunt trocar should fit the sheath and extend slightly over the sheath at the tip.

A 1.2mm disposable standard needle is suitable for outflow.

For tranguation purposes a twin sheath is used. This allows for switching the position of the working instruments and telescope.

A Xenon cold-light fountain provides a light with accurate color purity. The light cable that connects the telescope to the light source should be sufficiently long and flexible.

Instruments for arthroscopic surgery are:

- forceps, knives, and scissors;
- suction punch;

- mini-shavers;
- bipolar cautery;
- surgical lasers.

A mini-shaver or suction punch may be used to smooth surfaces of the disc and fibrocartilage or remove adhesions. Bipolar cautery has been used to coagulate tissue in cases of synovial bleeding or to cut the tissue.

During the last decade the surgical laser has become more popular. With the laser the wavelength of the transmitted light is most important. The energy of lasers with a wavelength in the far infrared spectrum, such as the carbon dioxide laser, is largely absorbed by water. The tissues in the joint have a high water content which would make this laser ideal, since most of the laser energy is absorbed by the superficial layers of tissue. The thermal damage zone is minimal, less than $70\mu\text{m}$. However, because of its long wavelength ($10.6\mu\text{m}$) it cannot be transmitted through a fiber-light cable without distortion. It is therefore not practical for arthroscopic surgery. The Neodymium YAG laser operates at a wavelength of $1.06\mu\text{m}$. Due to its short wavelength, the laser beam transmits easily through a flexible light cable and, as

a free beam, it also passes through water without being absorbed. The tissue penetration exceeds the tissue effect seen during surgery by 3–5 mm. The Neodymium YAG laser is excellent for coagulation. However, because the thermal damage zone is too large, it is not ideal for the TMJ. The Holmium YAG laser is a better alternative; it operates at a wavelength of 2.1 μm . The thermal damage zone is about 0.5 mm, making this laser ideal for the TMJ.

Arthroscopic procedure

Anesthesia

Routine diagnostic arthroscopy and minor arthroscopic surgery can be performed under local anesthesia. Arthroscopy under local anesthesia is more cost-effective than under general anesthesia. No assistant is required to manipulate the jaw and the patient can move the mandible normally.

Effective anesthesia of the joint area is achieved by blocking the auriculotemporal nerve posterior to the condyle and by infiltrating the subcutaneous tissue lateral to the joint (3–4 ml of lidocaine/epinephrine, 10 mg/ml).

The patient should be told that the anesthetic almost invariably affects the upper branches of the facial nerve and should be asked to remove ear-rings and contact lenses before arthroscopy. Sedation may be used if the patient so requires. In patients where advanced arthroscopic surgery is planned, general anesthesia is to be preferred.

Puncture

The arthroscopic examination should be performed with the patient in a supine position to reduce the risk of inducing a vasovagal reaction. The technique

for puncture has been described in several publications.^{9,10}

First, the upper compartment is distended with 2 ml of lidocaine which is injected slowly until resistance is felt. The additional injection of the anesthetic blocks any sensory input from branches of the posterior deep temporal and masseteric nerves supplying the anterior part of the TMJ. If no resistance is encountered after injection of 3 ml, the distension should always be stopped because it suggests the occurrence of leakage through the capsule into the surrounding tissue.

The so-called inferolateral approach gains good access to the posterior part of the upper compartment of the TMJ (Fig. 55.3). With this approach, access to the anterior recess is somewhat limited. However, from a diagnostic point of view, it is particularly important to examine the posterior part of the joint. This is also the best approach for puncturing the lower compartment. Alternative approaches to the upper compartment may be the endaural and anterolateral approaches (Fig. 55.3). The former may give a better view of the lateral part of the upper compartment; the latter provides better access to the anterior recess of the upper compartment. The anterolateral and endaural approaches are mainly used when arthroscopic surgery is intended.

It is questionable whether the lower compartment should be punctured at all. Even if successful, only the posterior non-functional parts of the disc and condyle are visualized and, moreover, it always involves at least some risk of damaging the lateral disc attachment. Routine puncture of the lower compartment should therefore be avoided.

Correct placement of the arthroscope should be confirmed through the telescope. An outflow portal is then created (inferolateral approach) about 5 mm anterior to and slightly below the arthroscopic sheath. Continuous irrigation is performed using isotonic

Fig. 55.3 Puncture directions for the TMJ. (1) Inferolateral. (2) Endaural. (3) Anterolateral.

saline solution. For more prolonged arthroscopic surgery, Ringer's solution may be a better alternative because it has been found to protect the chondrocytes and maintain the synthesis of proteoglycans.

Arthroscopic examination

The arthroscopic examination begins with identification of the arthroscopic landmarks – i.e. the boundary between the disc and the posterior disc attachment, the medial capsule, and the inferior part of the eminence. The arthroscope should always be moved slowly and gently between the various landmarks. Rotation of the arthroscope increases the field of vision considerably. The outflow should always be checked because if the needle becomes obstructed, considerable extravasation may occur in a short time. The irrigation pressure should be kept constant and low. In a small joint, such as the TMJ, this is best performed with a syringe by the assisting nurse. A total irrigation volume of 30–50 ml is usually sufficient for diagnostic arthroscopy.

Another problem may be the magnification of the structures by the telescope. The amount of magnification depends on the distance between the object viewed and the arthroscope. A ratio of 1:1 is obtained at a distance of 20–25 mm, which means that magnification is always present in a small joint such as the TMJ.

In the upper compartment the examiner should first identify the posterior disc attachment and the posterior part of the disc. The posterior disc attachment is the predominant location for inflammation and this part is therefore thoroughly examined for signs of inflammation, such as increased vascularity, capillary hyperemia, villi, or synovial hyperplasia.

The temporal cartilage and disc surface should then be evaluated. Signs of osteoarthritis, such as fibrillation, lesions in the fibrocartilage, and denuded subchondral bone, may be mainly located on the posterior slope of the eminence. Disc perforations are usually detected in the lateral, central, and posterior parts.

In some cases, the lower compartment can be examined through a large disc perforation from the upper compartment.

Arthroscopic surgery

In the field of orthopedic surgery, arthroscopic procedures have increasingly replaced open joint surgery. The duration of the postoperative period and the frequency of complications have thereby been reduced.

However, arthroscopic surgery of the TMJ is more difficult. The anatomic position limits the possibilities for surgery and the small size and the anatomy of the joint often give limited access for the instruments. The introduction of new instruments with fine dimensions and the surgical laser has increased the possi-

bilities for arthroscopic surgery of the TMJ. However, one should keep in mind that the increased access to the joint provided by small instruments does not necessarily imply that the procedure is effective. Many new instruments are ineffective as regards working capacity. An increased risk of broken instruments must also be considered. The complexity of the procedure can also make it rather time-consuming and some advanced arthroscopic procedures may take even longer than open surgery.

Technical aspects

Minor surgical procedures, such as lysis and lavage or partial synovectomy, can be performed under local anesthesia with or without sedation. More complicated procedures are best performed under general anesthesia. Draping is the same as for open TMJ surgery. The assistant can mobilize the mandible with the thumb through the drape behind the incisors or by using a towel clamp placed at the angle of the mandible.

The surgical procedures are best performed under direct visual control either with a double cannula or with triangulation. The double cannula needs one portal but the diameter of the instrument is rather big, about 4 mm, limiting the access to the anterior part of the joint. Triangulation is therefore frequently used instead (Fig. 55.4). It requires two portals but gives better access. Triangulation demands great skill by the surgeon, however, and a well trained assistant is needed. Training on cadavers and experience of open TMJ surgery are prerequisites.

The following surgical procedures can currently be performed:

- biopsy;
- lavage;
- lysis;
- disc repositioning;
- synovectomy;
- debridement and abrasion;
- restriction;
- intra-articular pharmacotherapy.

Synovial biopsy

Although arthroscopy is very accurate for diagnosing synovitis, recent studies indicate that a synovial biopsy may also be of value in the diagnosis.⁷ Current indications for synovial biopsy include chronic inflammatory conditions or benign tumors.

In the knee, biopsy under direct arthroscopic control has been shown to be the best because of the wide variation within the same joint. It is therefore necessary to use a second portal for the biopsy forceps. In small joints, such as the TMJ, a so-called semi-blind technique seems sufficient.^{11,12} First the area for performing the biopsy must be selected, then the arthroscopic sheath should be fixed in that position

Fig. 55.4 Triangulation using inferolateral and anterolateral approaches.

and the telescope removed. The biopsy forceps are then inserted, the sheath slightly withdrawn, the forceps opened, and the biopsy is then performed. The correct location should then be confirmed through the telescope. Recent studies in the TMJ have shown that the semi-blind technique has the same high accuracy as biopsy under direct visual control.¹² The type of biopsy forceps used seems to be more important. The forceps must be cup-shaped with sharp edges, in order to cut the tissue precisely, without compressing the specimen.

Lavage (arthrocentesis)

In patients with osteoarthritis of the knee, irrigation of the joint with isotonic saline solution or Ringer's solution has been found effective for giving pain relief and improving function. In osteoarthritis and synovial joint disease, there is an accumulation of microcartilagenous debris and inflammatory products. A thorough lavage will remove these irritating products, thus relieving symptoms and resulting in more favorable conditions for repair.

The procedure is relatively easy to perform and requires very few instruments. In its simplest form, a 1.2mm needle is used for outflow (Fig. 55.5). The irrigation is performed with a syringe and a 0.6mm needle placed in the posterior recess of the upper compartment. A total of 100 ml of isotonic saline solution is slowly injected, and the outflow is constantly checked. The patient may move their jaw slightly during the irrigation.

TMJ lavage is a quick, inexpensive and non-invasive method with hardly any complications. The outcome has been good in several follow-up studies.¹³⁻¹⁸ The disadvantage with simple lavage or arthrocentesis is that the irrigation is not effective for breaking up adhesions or mobilizing the disc which is the main problem in, for example, chronic closed lock and osteoarthritis.

Lysis

Adhesions frequently occur in patients with chronic closed lock, osteoarthritis, and rheumatic disease. These are thought to result from repeated inflammatory episodes and require lysis or removal to improve function. The lysis can be performed blindly, using a blunt trocar with sweeping movements from anterior to posterior (Fig. 55.6). An alternative is to use the Holmium YAG laser under direct arthroscopic control, as described by Koslin.¹⁹

Combined lysis and lavage after arthroscopic diagnosis provides a better result than lavage only according to recent studies.^{15,20-22}

Disc repositioning

Disc repositioning has been performed extensively in open TMJ surgery (see Chapter 56).

A few studies have reported on arthroscopic disc repositioning.^{23,24} First an anterior release is performed with a laser, the disc is then pushed posteriorly and held in position while a suture is passed through the posterior part of the disc and then tied to either the anterior wall of the meatus or the subcutaneous tissue posterior to the joint. This technique requires considerable skill and is time-consuming. The passing of the suture through the avascular portion of the disc is questionable. A better alternative may be to create scar tissue with the laser in the posterior disc attachment and thereby stabilize the disc in the correct position.

Good short-term results have been reported with disc suturing,²³ but there is a need for long-term outcome studies using MRI.

Synovectomy

It seems an attractive principle to intervene early in the disease process in patients with rheumatic joint

Fig. 55.5 Irrigation (arthrocentesis) of the TMJ. (a) Irrigation using two needles. (b) During arthroscopy using the arthroscopic sheath for outflow providing effective irrigation.

Fig. 55.6 Lysis of adhesions. (a) Simplified drawing of adhesion between the temporal fibrocartilage and the disc. (b) Semi-blind release of adhesions in the joint.

disease and to remove areas of focal granulation in the synovial lining in order to prevent spread to the fibrocartilage and disc. In the knee, controversy exists regarding the long-term effect of arthroscopic synovectomy. However, it has been shown to reduce pain and improve function for up to 5 years.²⁵

Synovectomy should be performed under direct arthroscopic control using a Holmium YAG laser that vaporizes the tissue, which is then removed by irrigation (Fig. 55.7). At present, there are few outcome studies of synovectomy of the TMJ.

Debridement and abrasion

Joints with osteoarthritis and arthritides frequently display irregularities of the fibrocartilage and disc. These irregularities may interfere with the smooth functioning of the joint and, if so, they must be removed. They can be removed with a mini-shaver. However, the use of a shaver in a small joint like the TMJ requires considerable surgical skill and removal should always be done under direct arthroscopic control in order to avoid complications such as damage to vessels and nerves close to the joint capsule. The Holmium YAG laser is a better alternative for the debridement because of improved access to the more distant parts of the joint.

Abrasion arthroplasty has previously been discussed in the orthopedic literature. However, much controversy exists regarding its efficacy. The procedure for the TMJ was described by Quinn in a preliminary study²⁶ but requires further evaluation.

Fig. 55.7 Simplified drawing of laser synovectomy in the TMJ. In patients with hypermobility, the laser may also be used in a coagulating mode to create scar tissue, thereby limiting translation of the disc-condyle complex.

Restriction

Temporomandibular joint hypermobility or recurrent luxation may also be treated arthroscopically. This method has focused on producing scar tissue in the the posterior disc attachment, thereby limiting forward translation of the disc-condyle complex. Under arthroscopic control, a sclerosing solution is injected subsynovially in the posterior disc attachment.²⁷ Another possibility is to use cautery or laser.²⁸ The laser is used in a coagulating mode to create scar tissue in the posterior disc attachment (Fig. 55.7). A third method is to pass a suture through the posterior part of the disc and then tie it to the anterior wall of the meatus.²⁹ Short-term outcome studies have shown good results with all three methods. However, as yet no long-term evaluation has been published.

Intra-articular pharmacotherapy

Intra-articular injections with corticosteroids and hyaluronan have been used in combination with TMJ arthroscopy. Both of these drugs have alleviated pain and improved mandibular function in patients with chronic arthritis.³⁰ Moreover, hyaluronan seems to have a good effect on clicking joints.³¹

At the end of the arthroscopic procedure corticosteroids are usually injected. However, in the TMJ this always entails extravasation of the steroid to some extent through the portals created, which, in turn, may cause atrophy of the subcutaneous tissue. It is therefore better to inject easily dissolvable steroids into small joints such as the TMJ and preferably to wait 1 week after arthroscopy before doing this.

Hyaluronan should also be injected strictly intra-articularly, because an extra-articular injection causes severe pain.

Postoperative care

Arthroscopy under local anesthesia has many advantages compared with that performed under general anesthesia and the patient is ready to go home after only 1 hour's rest in the clinic. Any anesthetic effect on branches of the facial nerve has usually disappeared by then.

The patient is given a simple training program. A physiotherapist is contacted if needed. Control of any parafunctional habits is also maintained postoperatively. Information about hygiene and food is then given to the patient. In cases of postoperative pain, a mild analgesic is prescribed.

Prophylactic antibiotics may be given to patients at high risk for infections (immunodeficiency, heart valve prosthesis, etc.). In normal cases, there is no need for prophylactic antibiotics.

If the arthroscopic procedure is performed under general anesthesia the postoperative care follows the protocol of that for open TMJ surgery. Usually, the

procedure can be performed as day-case surgery limiting the cost for the patient and society.

Complications

Intraoperative and postoperative complications are seldom associated with minor arthroscopic procedures. This accords with data in the orthopedic literature regarding knee joint arthroscopy.³² However, it should be emphasized that a complication in the TMJ area can be disastrous for the patient. A few such complications have been reported, concerning damage to the middle ear and the facial nerve.^{33,34} In arthroscopic surgery, particularly the more complicated procedures, the risk of complications is obviously greater. An adequate knowledge of the external and internal anatomy of the TMJ is a prerequisite for clinical use of the arthroscope. Preoperative radiographic examination should include CT. Training on cadavers before clinical use is recommended. Experience of open TMJ surgery facilitates the management of a complication.

Possible complications include:

- vascular injury;
- extravasation;
- scuffing of cartilage;
- broken instruments;
- otologic complications;
- intracranial damage;
- infection;
- nerve injury.

Vascular injury

Vascular injury is rare. Carter and Testa noted hemorrhagic complications in 1.8% of the cases in a survey of 2225 TMJ arthroscopies.³⁵ In about 80%, the temporal vessels were involved.

If well designed trocars are used, these rarely cause bleeding during puncture of the TMJ. More often it is the outflow needle that causes the bleeding, especially if the needle is difficult to position. The bleeding is usually venous in origin and easily controlled, using a tamponade. In persistent cases the cutaneous incision can be extended slightly and the source of the bleeding is sought, and ligated or controlled with cautery. Intra-articular bleeding may occur in more advanced arthroscopic surgery. The protocol suggested by McCain seems appropriate.³⁶ All instruments are first removed and the condyle is then moved to the compartment where bleeding has occurred and is kept there for about 5 minutes. The instruments are then reinserted to irrigate and debride clots that may have formed. If this procedure does not work, the joint must be opened and bleeding controlled.

Intra-articular hemorrhage is common in trauma to the mandible.³⁷ However, the accumulated blood

seems to be resorbed within a couple of weeks.³⁷ Thus, the risk of developing an arthrofibrosis because of intra-articular hemorrhage is low.

Vascular malformations, such as arteriovenous fistulas, resulting from TMJ arthroscopy are unlikely, but they have been reported.^{38,39}

Extravasation

Excessive extravasation of irrigation fluid into the surrounding tissue sometimes occurs. In prolonged arthroscopic surgery, the risk becomes greater and cases of extensive edema in the upper airway with subsequent postobstructive pulmonary edema have been reported.⁴⁰ If the surgeon or the nurse always checks the outflow, this is unlikely to occur.

Scuffing

The cartilage may be scuffed by the trocar during the puncture. The scuffed fibrocartilage should not be mistaken for arthrotic changes. This lesion can be avoided if the trocar is directed towards the crest of the glenoid fossa until it touches the bone. The sharp trocar is then exchanged for a blunt one which is directed slightly inferiorly to slip into the upper compartment.

Broken instruments

Instruments that break during arthroscopic manipulation result in an unpleasant complication. Such complications have been reported by McCain⁴¹ and Tarro.⁴² They show that the surgeon must be trained in open TMJ surgery, since this may be the only way to retrieve a broken instrument. For many reasons, a broken instrument should not be left in place. One reason is that it may be potentially dangerous, another reason is that it may be blamed for a poor result.

This complication can be avoided by using a correct technique and impeccable instruments.

Otologic complications

A few otologic complications have been noted in association with TMJ arthroscopy. Van Sickels *et al.* reported a case with perforation of the tympanic membrane and partial dislocation of the malleus.³³ Appelbaum *et al.* described three patients who largely lost their hearing.³⁴ Serious complications, such as those mentioned above, can be avoided only by proper training in TMJ anatomy and practice on cadavers before the clinical use of TMJ arthroscopy.

The influence of TMJ arthroscopy on normal hearing has been evaluated by audiometric measurements pre- and postoperatively.^{43,44} Both studies indicate that the risk of adverse effects on hearing is extremely low.

Intracranial damage

Damage to intracranial structures during TMJ arthroscopy must not occur. Nevertheless, such damage has been reported.⁴⁵ The roof of the glenoid fossa can be extremely thin but it is the author's experience from autopsy studies that it takes considerable force to penetrate the roof of the glenoid fossa, even with a sharp trocar. In patients whose cartilage and bone show marked destruction (e.g. advanced rheumatoid arthritis) great caution must be exercised and routine radiographic examination supplemented with CT.

Infection

In an extensive review of 3146 patients (4831 joints) by McCain in 1992,⁴⁶ where complications associated with TMJ arthroscopy were also reported, the frequency of infections was low (15 cases; 0.3%). This brings into question the common use of prophylactic antibiotics. The author has performed more than 1500 TMJ arthroscopies without using any antibiotics and no patient has developed an infection. Considering recent reports on increase in the frequency of bacterial resistance to antibiotics, it seems unnecessary to use antibiotic prophylaxis in routine cases.

Nerve injury

Injuries to nerves are almost never associated with TMJ arthroscopy. In more than 4800 TMJ arthroscopies, McCain *et al.* reported only three cases (0.06%) with permanent nerve damage.⁴⁶ Thus the frequency is about the same as that reported for knee joint arthroscopy. The auriculotemporal and facial nerves are most often involved. Excessive extravasation of irrigation fluid may exceptionally have a transient effect on the infraorbital, inferior alveolar, and lingual nerves.

Concluding remarks

Similar to developments in the field of orthopedic surgery, TMJ arthroscopy has become an important method for diagnosis and treatment. Its accuracy in diagnosing TMJ diseases is high and simultaneous biopsy can be performed to improve diagnosis. Complications are minor and infrequent. The various new surgical methods show good short-term results. A recent retrospective study of 488 arthroscopies showed that only 20% needed additional surgeries and a randomized clinical trial has shown comparable good results when comparing arthroscopic lysis and lavage with discectomy.²¹ The application of surgical lasers to the TMJ has extended the possibilities for arthroscopic surgery. Some arthroscopic procedures, such as the frequently performed lysis and lavage, can be done under local anesthesia in an outpatient clinic. It is cheaper than open TMJ surgery since it

means a shorter hospitalization and little, if any, sick leave for the patient. Finally, arthroscopy provides unique possibilities for research to elucidate the complicated etiopathogenesis of TMJ disorders.

Chapter 56

Temporomandibular Joint Surgery

Anders Holmlund

The temporomandibular joint (TMJ) has many similarities with other synovial joints and thus the joint diseases that occur in other body joints are also found in the TMJ. However, the TMJ also shows specific features regarding anatomy and function which have to be considered when surgical treatment is intended.

This chapter will discuss etiology and pathogenesis for common TMJ diseases and propose diagnostic criteria and indications for surgery based on recent research. The techniques for established surgical procedures are described as well as common complications. The procedures are critically reviewed regarding outcome and suggestions are given on how to further develop TMJ surgery.

Development of temporomandibular joint surgery

Many of the temporomandibular joint (TMJ) diseases that we see today were also recognized centuries ago. However, it took until the late 19th and early 20th centuries before it was possible to perform TMJ surgery. Many of the procedures that we perform today are in fact improvements and modifications of surgical techniques first performed by these pioneers. Examples of this are Annandale who performed the first TMJ disc repositioning in 1887¹ and Lanz who performed the first discectomy in 1909.² TMJ ankylosis was operated on in the 1850s and surgical reports by Rizzoli and Verneuil³ described gap-interposition of gutta-percha and temporalis muscle.

The most common TMJ problem leading to TMJ surgery has been, and still is, TMJ clicking and locking. Pringle in 1918⁴ and Wakely in 1929⁵ described disc displacement and contributed to the understanding of disc displacement. A more detailed description was made later by Karl Bohman,⁶ who also presented results from more than 50 patients.

Schwartz⁷ in the 1950s and Laskin⁸ in the 1960s pointed out the importance of muscle disorders and psychosocial mechanisms as part of TMJ symptoms. In the 1970s, there was a renewed interest in the role of the disc after publications by Farrar and McCarty.⁹ Later, Eriksson and Westesson,¹⁰ Wilkes,¹¹ Hall,¹² and Holmlund¹³ have further contributed to the development of TMJ surgery. It is beyond the aim of this chapter to go deeper into the history of TMJ surgery,

but it cannot be emphasized enough how valuable it is for the contemporary surgeon to also study the past.

Classification of surgical TMJ disease

TMJ disease can be classified as follows:

- Mechanical disorders:
 - reciprocal clicking – disc displacement;
 - mandibular dislocation.
- Degenerative joint disease:
 - chronic closed lock – disc displacement;
 - osteoarthritis.
- Chronic polyarthritis with TMJ involvement.
- TMJ trauma:
 - contusion;
 - intracapsular fracture;
 - condylar neck fracture.
- TMJ abnormalities:
 - congenital;
 - acquired.
- TMJ tumors:
 - benign;
 - malignant.
- TMJ infection.
- Extra-articular connective tissue diseases.

The widely used term "temporomandibular dysfunction" (TMD) is not used in this classification. It is the authors' opinion that this term should be avoided when a surgical classification is intended as it makes no separation between muscle conditions and true joint afflictions. This does not mean that muscle conditions have no importance. It simply means that these conditions are not to be treated surgically except for a few rare cases. Moreover, the term "internal derangement" is avoided in this classification. Instead, the two clinical variants of disc displacement (reciprocal clicking and chronic closed lock) are classified under "mechanical disorders" and "degenerative joint disease" respectively. A rationale for this will be given in the following paragraphs.

Reciprocal clicking and chronic closed lock

Biological background

Based on recent research the following statements can be made:

- Reciprocal clicking is common and affects at least 7% of the adult population.¹⁴
- The reciprocal click correlates with a displacing disc and a callus formation in the posterior part of the disc.¹⁵ Except for the callus formation the disc has a normal structure. The fibrocartilage is unaf-

ected and thus no osteoarthritic changes are found.¹⁵

- In joints with reciprocal clicking a mild T-cell dominated inflammation with interleukin (IL)-1 α and β expression is found.¹⁶

Chronic closed lock is characterized by a permanently displaced disc. It may be preceded by reciprocal clicking but in many patients it is not.¹⁵ It is also the author's impression that there are no differences with regard to tissue appearance between patients with or without previous reciprocal clicking.¹⁵ The disc shows clear degeneration.¹⁵ The fibrocartilage shows varying degrees of osteoarthritis.¹⁵ A chronic inflammation is present in the synovium and both T-cells and macrophages are present.¹⁶ Moreover, the cytokine expression is more complex. In addition to IL-1, tumour necrosis factor (TNF) α , transforming growth factor (TGF) β and, in particular, interferon- γ are also expressed.¹⁶ As a result of the prolonged chronic inflammation, adhesions between the disc and the temporal fibrocartilage may form, further limiting the translation of the disc-condyle complex.

The relationship between reciprocal clicking and chronic closed lock has been described in a recent publication by the author.¹⁷

Surgical implications

Only a small number of patients with reciprocal clicking develop intermittent locking or a socially disturbing loud clicking that should be considered for surgery. The treatment has to consider the displaced disc but more importantly the callus formation in the posterior part of the disc. This can be done by removal of the callus, by repositioning of the disc, by altering the condylar position, or by increasing the joint space.¹⁷

In chronic closed lock, there is an ongoing degenerative process in the disc which seems to spread from posterior to anterior.¹⁵ Moreover, a (probably) secondary chronic synovial inflammation develops, and as a result of this adhesions form between the disc and the temporal fibrocartilage. The disc is permanently displaced anteriomedially which also impairs the translation of the condyle.

In about 40% of the patients with chronic closed lock, the pain may subside and function improve.¹⁸ The reason for this is not clear but it seems to correlate with development of a disc perforation which releases the tension and blockage caused by the displaced disc.¹⁹ In these patients, the development of osteoarthritis has also been found radiographically.¹⁹ Symptomatic treatment for a certain period may thus be used, but the problem is that it may take up to 2 years before a spontaneous remission is seen. Moreover, as only about 50% of the patients will improve spontaneously, it is not possible to predict if the patient will fall into this group or will continue to have symptoms.

It should be understood that in chronic closed lock (as well as many other joint diseases), there is no cure for the disease. Until the disease has been explained, we can, at best only prevent further development of the disease, improve mandibular function, and reduce pain. This may be achieved by manipulating the blocked disc and by breaking up the adhesions. Once translation of the disc–condyle is improved, lubrication and nutrition will also improve, providing the basis for tissue healing. The removal of irritating debris and inflammatory mediators may also contribute to improvement (see Chapter 55).

Surgical approaches to the TMJ

Preparation of the surgical site

Preparation and draping should expose the entire ear and also the lateral canthus of the eye. The hair may be shaved in order to keep the draping in place and to expose the temporal area. A small sponge is placed into the external auditory canal. An anesthetic with vasoconstrictor may be used to control subcutaneous bleeding after incision. However, the injection should only be kept superficial as anesthesia in the deeper tissue layers may hamper the use of a nerve stimulator. The skin incision may be marked with dye but there is usually a natural skin fold to follow.

Incision

The standard approach to the TMJ is the preauricular approach (Fig. 56.1a). It uses the preauricular skin fold and, if needed, may be extended superiorly and slightly anteriorly. Normally, when an intra-articular procedure is intended there is no need for a superior or anterior extension of the incision but in cases where access to the area anterior to the eminence is needed such an extension of the incision is practical.

Some surgeons prefer to bring the incision behind the tragus (endastral incision) in young individuals, advocating that this will reduce the visible scar. It is true that the preauricular incision in a few young patients creates a scar that is slightly erythematous, but this will blanch within a couple of months. However, a tragal extension can create more of a problem from an esthetic point of view.

The retroauricular incision has been suggested, mostly in older publications. This approach comprises a curved incision behind the ear and thereby the incision is completely hidden. The access to the anterior part of the joint is somewhat limited. The major drawback of this approach is that it involves transection of the external auditory canal. Problems such as stenosis of the ear canal and infection have been reported.

In summary, the preauricular approach with or without temporal extension provides access for almost all TMJ procedures, including surgery for trauma, ankylosis, and tumors.

Dissection of the joint

The dissection commences in the superior part of the incision (Fig 56.1b–d). The temporalis fascia is exposed and any vessels running posteriorly are ligated or cauterized. The fascia is then followed inferiorly down to the superior part of the zygomatic arch. The temporal artery and vein may be ligated if they interfere with the exposure of the joint. The auriculotemporal nerve usually runs together with the artery and vein and may be dissected free and retracted anteriorly. It is often rather thin and may therefore be either torn or accidentally transected during the dissection. As a consequence there will be a decreased sensitivity in the skin over the TMJ area. The sensitivity will reappear at least partly in most patients within a year and even if a hyposensitivity is permanent, this seems not to disturb the patient. The facial nerve is rarely a problem. In a few cases the temporal branch may be encountered close to the joint capsule anteriorly. If the dissection is kept close to the tragus this is avoided. However, there is always a risk of traction on the nerve from the anterior retractor. It will occur in about 6% of cases. This temporary palsy will subside within 3 months.

The dissection is then continued with an antero-superior incision through the superficial layer of the temporalis fascia which is then extended inferiorly. The scissors are used to identify the zygomatic arch. An almost constant finding is a fairly large vein running over the zygomatic arch in a superior direction. This vein is a useful landmark for the anatomical location of the glenoid fossa. After exposure of the zygomatic arch, the lateral capsule is easily found inferiorly. The structures anterior and inferior to the capsule are protected with retractors. A horizontal incision in the superior part of the capsule provides access to the upper compartment. There is usually a recess between the lateral capsule and the lateral disc attachment but sometimes the capsule has to be transected vertically to gain access to the inferior part of the lateral disc attachment. The retractor is now placed between the capsule and the disc and the lateral disc attachment is cut while lifting the structure somewhat. This protects the condylar cartilage from being traumatized. Condylar retractors are now placed anterior and posterior to the condyle. In order to open up the joint space, a 1.1 mm Kirschner wire is now drilled into the condyle and zygomatic arch and a retractor is positioned and the joint space widened. If the joint space is not opened up it may be difficult to visualize the disc, especially in the medial part. If a discotomy is performed it may result in incomplete removal of the medial part of the disc.

Closure of the incision is made in the usual manner beginning with the lateral capsule and the temporal fascia and then a few sutures in the deeper subcutaneous tissue and finally a running 4/0 subcuticular suture to close the skin.

Fig. 56.1 Surgical dissection of the TMJ. (a) Preauricular incision line. (b) Zygomatic arch and lateral capsule exposed. (c) Lateral capsule opened and condylar retractors placed. (d) Kirschner wires drilled into the eminence and condyle and a Wilkes self-retaining retractor (W. Lorenz Surgical, Jacksonville, FL) applied to increase access to the joint.

Reciprocal clicking

Clinical diagnosis

The patient usually complains of loud clicking and catching of the joint. The clinical examination reveals a reciprocal click (Fig. 56.2). This sign is strongly correlated to a displacing disc and callus formation in the posterior part of the disc. Thus, a diagnosis based on clinical examination is sufficient and there is no need for radiographic examination unless surgery is intended. In most patients the reciprocal clicking also occurs in protrusion and laterotrusion to the opposite side. The patient experiences pain only when the joint locks temporarily. There is usually no pain over the joint area upon palpation. Mandibular movements are usually normal and radiographic examination shows normal features in the majority of patients.

Surgical treatment

Disc repositioning

Disc repositioning means that the anteriorly displaced disc is surgically repositioned back to its original position on the condyle (Fig. 56.3).

Biological considerations

The central part of the disc is thin and avascular and has the properties to take up the load during function. It also facilitates the sliding of the disc–condyle complex down the posterior slope of the eminence.

In TMJs with reciprocal clicking the disc is displaced anteriorly and there is a callus formation in the posterior part of the disc. When surgery is planned it is therefore important to address the altered position and also the fact that the disc is deformed. If the callus is not removed, or at least reduced, the disc will displace again. A problem is that the callus is usually most prominent in the posteriomedial part where access is limited and sometimes even a large part of the disc itself has been displaced medially.

Outcome studies

Disc repositioning has been performed extensively and there is a number of case series reported. The overall results have been good.²⁰ There is no convincing evidence (e.g. magnetic resonance imaging (MRI) studies) showing that a repositioned disc remains so after surgery. In general, there is a lack of randomized clinical trials and the outcome criteria or end-points are poorly defined. Therefore, the procedure needs to be validated in randomized clinical trials

(b)

Fig. 56.2 Patient with reciprocal clicking and catching of the right TMJ. (a) Maximum opening before the click. (b) Manipulation of the TMJ with the thumb. (c) Maximum opening after click.

where it is compared with a proper reference procedure.

Complications

There are very few complications reported with the methods described above. A temporary palsy of the temporal branch of the facial nerve is seen in about 6% of cases. A slight but clinically insignificant hyposensitivity in the skin anterior to the ear may be found in most patients. Deep infection is very infrequent. Superficial infection adjacent to a remaining suture may be seen occasionally. Whether a prophylactic antibiotic should be given or not remains unanswered. Until such a study has been performed, the author routinely prescribes clindamycin 600mg IV given 1 hour before surgery. Serious scar formation is extremely rare. Malocclusion, demanding slight occlusal adjustment, may occur in a few patients.

Modified condylotomy

The hypothesis of this method is that if the position of the condyle is altered the load on the posterior disc attachment will be reduced, which in turn will facilitate a spontaneous repositioning of the disc on the

Fig. 56.3 Simplified drawing showing surgical repositioning of the disc. (a) Displaced disc. (b) Disc after surgical repositioning.

condyle (Fig. 56.4). In the knee, the same method has been used in the past by performing an osteotomy of the tibia, thereby changing the load on the meniscus.

The technique comprises an intraoral vertical ramus osteotomy via an incision of the buccal fold posteriorly. The posterior segment containing the condyle is allowed to drop a few millimeters but the segment is not fixed to the distal portion of the mandible. The wound is sutured and intermaxillary fixation with elastics is then applied and held for 2 weeks.

Outcome studies

There have been a few long-term follow-up studies done but no randomized clinical trials comparing modified condylotomy with, for example, discectomy.²¹ These studies also show considerable drop-out of patients during the follow-up period, decreasing the value of the studies. In conclusion, modified condylotomy may also be a useful method for treatment of reciprocal clicking and catching of the TMJ but it has to be validated in comparative randomized studies comparing it with discectomy.

Complications

Complications are usually minor. Wound infection may occur but is usually not a problem. The condyle may displace in some cases and create an open bite on the operated side.

Discectomy

Biological considerations

Discectomy treats both the displaced disc and the problematic callus in the disc and does it effectively (Fig. 56.5). Thus, the loud click disappears as well as the catching of the joint. However, removal of the disc also has some negative consequences. In most cases a slight reduction of the translation of the condyle is seen at follow-up, probably because of a slight scar tissue formation in the joint. Crepitation is common as are radiographic signs of remodeling or

Fig. 56.4 Simplified drawing showing modified condylotomy of the TMJ.

Fig. 56.5 (a) Excision of the disc. (b) Exposure of an interfering osteophyte on the condyle.

arthrosis of the articular surfaces.²² However, it seems that this arthrotic-like appearance does not correlate with impaired function or pain.

Outcome studies

Discectomy without replacement has been thoroughly evaluated in well designed long-term follow-up studies.^{13,22–24} In prospective 5-year follow-up studies at four different oral and maxillofacial centers in Sweden the success rates were high, about 85%, and were also stable over time. Moreover, in a long-term retrospective study (mean follow-up 29 years) the results were very good. No patient had TMJ pain and the maximum opening was more than 39 mm. Similar to what was found in the prospective studies, crepitation and radiographic signs of arthrosis were common.

In conclusion, discectomy is thoroughly evaluated and should be regarded as the first choice for surgical treatment in patients with TMJ reciprocal clicking. Discectomy should also be the reference procedure in randomized clinical trials when new surgical methods are to be evaluated.

Complications

The complications are the same as for disc repositioning surgery.

Disc replacement

In the same context as discectomy, disc replacement must also be discussed. Several methods using alloplastic materials as well as autogenous tissue have been used. Alloplastic materials used in the past include Silastic and Proplast, which are no longer used because of complications including fragmentation and giant cell reactions. The implants were held in place with sutures or screws drilled into the zygomatic arch. Among the autogenous procedures suggested for use today the temporalis muscle flap seems to have the greatest potential.

Outcome studies

There are no randomized clinical studies comparing disc replacement with discectomy without replacement and the reported success rates for disc replacement surgery have not exceeded those of discectomy without replacement.

Complications

Compared with discectomy without replacement there is an increased risk of complications (inflammatory reactions and deep infection) when alloplastic materials are used. Donor site morbidity may occur when autogenous tissues are used.

Mandibular dislocation

Epidemiological studies have revealed an increased incidence of general joint hypermobility in children, in women compared with men, and in some racial groups (Eskimos and Chinese).²⁵

Clinically it is difficult to decide when the TMJ should be regarded as hypermobile. The reason for this is the great variation in translation capacity between normal subjects. In TMJ patients, based on TMJ arthrographic findings, a frequency of 29% has been reported. Symptomatic hypermobility of the TMJ has been recently investigated in children, young adults, and adults.²⁶ Girls/females were predominant. The overall prevalence was about 18% in 15-year-old children, 19% in 22-year-old young adults, and about 15% in 43-year-old adults. Risk factors for the development of symptomatic hypermobility were gender (females), race other than Caucasian, masticatory muscle pain, and increasing maximum mouth opening.

TMJ hypermobility may be subclassified into:

- acute dislocation;
- recurrent dislocation;
- long-standing dislocation.

Acute dislocation has been known since the time of Hippocrates or even earlier. Although rather dramatic in its appearance it is quite easily managed. Most acute dislocations occur only once. Recurrent dislocations are rare, but the situation is often very disturbing for the patient with frequent visits to emergency units. Another category of recurrent luxations are the patients with so-called habitual luxations. These patients can dislocate and reposition the mandible at will and therefore rarely pose a clinical problem. Yet another category are the very few patients with long-standing dislocations. These patients are usually old and chronically ill with a variety of neurological disorders making them unable to communicate their

problem. The author has had five such patients through the years where the mandibular dislocation was not diagnosed by the nursing personnel.²⁷

Clinical diagnosis

Clinical diagnosis is usually not a problem. In bilateral dislocations there is a frontal open bite, in unilateral dislocations there is a deviation of the mandible to the opposite side and a lateral open bite on the same side (Fig. 56.6). The condyle is not seated in the glenoid fossa and thus the area anterior to the tragus appears "empty". Radiographic examination confirms the dislocated mandibular condyles.

Differential diagnosis involves traumatic contusion of the TMJ and possibly also unilateral growth of the condyle. It is important to have a proper medical history to rule out these conditions. For the inexperienced surgeon a radiographic examination may be helpful.

Surgical treatment

Acute dislocation

Acute dislocation is best managed with manual repositioning. In the author's experience, manual repositioning is easy and quick provided that a proper technique is used. The patient should be reassured and then the repositioning should be done as quickly as possible without any unnecessary delay (Fig. 56.7). In order to reposition the mandible it is important to press downwards on the mandibular molars and avoid pushing the mandible backwards. If some time has elapsed since the dislocation occurred, either local anesthesia over the joint or sedation/analgesic may be given. Only when the dislocation has persisted for days may it be necessary to perform the repositioning under general anesthesia.

Usually, there is no need for any bandage. In cases where there is a tendency for recurrent luxation a

Fig. 56.6 Patient with recurrent dislocation of the mandible. (a) Clinical appearance. (b) Radiographic examination confirming the dislocated condyles.

loose intermaxillary fixation may be used for a week or so.

Recurrent dislocation

Several methods for management of recurrent dislocation have been proposed through the years, such as blocking procedures, anchoring procedures, methods inducing scar tissue, myotomy, eminectomy, and discectomy. Both open surgery and arthroscopic procedures have been described in the literature.

Myotomy was first described by Bohman in 1949 (Fig. 56.8a).²⁸ The method comprises sectioning of the muscle attachment anterior to the condyle. However, reattachment of the muscle seems to occur and Laskin therefore suggested the use of a Silastic sheet anterior to the condyle to prevent reattachment of the muscle.²⁹ In 1988 Sindet-Pedersen reported on intraoral myotomy of the pterygoid muscle where scar tissue was also induced anterior to the condyle.³⁰

Eminectomy was first described by Myrhaug in 1951 (Fig. 56.8b).³¹ The rationale is to facilitate spon-

taneous repositioning instead of blocking the excessive translation. Thus, the eminence is reduced as far as possible from the lateral side. The backward translation of the disc-condyle complex is facilitated but it is the author's experience that ingrowth of the lateral capsule also contributes by making the joint more rigid. An arthroscopic method for eminectomy has also been reported recently.³²

A blocking procedure that gained popularity in the 1980s was the Le Clerc procedure (Fig. 56.8c).³³ An osteotomy is performed in the zygomatic arch anterior to the eminence and the arch is then down-fractured and placed under the eminence, blocking disc-condyle translation anterior to the eminence.

Discectomy has also been suggested, for example by Wakely.³⁴ This method addresses the problem that hypermobility and mandibular dislocation often also have an associated disc displacement with clicking. Discectomy seems to both reduce the translation of the condyle (probably because some scar tissue is formed) and eliminate the disc-related catching of the joint.

Fig. 56.7 Patient with acute mandibular dislocation. (a) Before repositioning. (b) Manual repositioning. (c) After repositioning.

Fig. 56.8 Surgical methods for treatment of recurrent mandibular dislocation. (a) Myotomy of the lateral pterygoid muscle. (b) Eminectomy. (c) Le Clerc procedure.

Outcome studies

In general, there is a lack of randomized clinical trials. It is problematic that even single follow-up studies comprise small numbers. Considering these limitations eminectomy and discectomy seem to be the methods of choice. Arthroscopic methods have to be further evaluated.

Complications

Regarding myotomy and eminectomy there is an increased risk of injury to the temporal branch of the facial nerve as the dissection has to be extended anterior to the eminence. For discectomy, the risk of complications is very low, as previously mentioned.

Chronic closed lock and osteoarthritis

Chronic closed lock and osteoarthritis are described under the same heading as they frequently occur together.

In its early phase, chronic closed lock may show no lesions in the fibrocartilage but sooner or later they will appear. In a recent study, all patients with chronic

closed lock showed osteoarthritic changes in the TMJ operated on.¹⁵ Chronic closed lock may or may not be preceded by reciprocal clicking.¹⁷ Chronic closed lock usually has a rapid onset, a so-called acute closed lock. The reason for this may be a tear of the posterior disc attachment with a resulting anterior displacement of the disc.

Osteoarthritis (also called degenerative joint disease) is thought to be a primarily degenerative disease of the cartilage. Synovial inflammation may occur secondary to the primary disease process. Cartilage debris and inflammatory mediators are thought to provoke the synovitis. Osteoarthritis may also occur in a generalized form. The criterium for this diagnosis is that more than three joints (the spine excluded) should be affected. The TMJ may also be affected.

Clinical diagnosis

Chronic closed lock usually shows the following clinical features (Fig. 56.9):

- pain in the TMJ upon mandibular movements;
- laterotrusion to the opposite side is reduced and painful while laterotrusion to the same side is not;

Fig. 56.9 Patient with chronic closed lock of the left TMJ. Red wax indicates the dental midline. (a) Maximum opening reduced and deviation of the mandible to the affected side. (b) Laterotrusion to the affected side is normal. (c) Laterotrusion to the opposite side is reduced.

- maximum opening and sometimes also protrusion deviates towards the affected side;
- maximum opening and protrusion are reduced;
- the affected TMJ is tender to palpation laterally and sometimes also posteriorly.

Normally, there are few muscle symptoms. If present, these are localized to the jaw muscles on the affected side. If parafunction is also present, muscle symptoms may be more prominent.

Radiographic examination may or may not show arthrotic changes of the subchondral bone (erosion, sclerosis, flattening, reduced joint space). MRI findings are an anteriorly (sometimes medially) displaced disc and some fluid in the joint indicating inflammation.

Osteoarthritis is clinically diagnosed if there is crepitation in the joint. Crepitation has been found to correlate well with manifest osteoarthritis and disc perforation. However, early phase osteoarthritis can only be diagnosed arthroscopically. Clinical signs and symptoms may be similar to those of chronic closed lock but some patients have quite good mobility of the joint. In these patients the complaints are mainly joint pain when opening and chewing. In some patients, the inflammation may be more pronounced and sometimes an interfering osteophyte may occur (Fig. 56.10).

Arthroscopy will reveal advanced destruction of the fibrocartilage, chronic inflammation, and adhesions. Radiographic examination shows arthrotic changes in the subchondral bone and reduced joint space. MRI may add to the diagnostic information by demonstrating a displaced and deformed disc.

Surgical treatment

In chronic closed lock, the disc is permanently displaced, resulting in a load on the vascularized and innervated posterior disc attachment. The translation will be impaired by the displaced disc as well as

Fig. 56.10 Patient with osteoarthritis. (a) Interfering osteophyte on the condyle. (b) Excised disc with a large perforation.

adhesions resulting from the chronic synovitis. The reduced translation, in turn, impairs the vascular supply to the posterior disc attachment and, if this is prolonged, the nutrition and lubrication of the joint will be affected, aggravating the degenerative process.

The TMJ has a marked capacity for adaptation and repair. Thus, the TMJ may develop a spontaneous remission similar to that seen in other joints. This has also been shown in a study by Kurita *et al.*¹⁸ who found that about 40% of the patients with chronic closed lock obtained a spontaneous remission within

2.5 years after only symptomatic treatment with non-steroidal anti-inflammatory drug (NSAID) medication. However, this and previous studies have not been able to predict which patients will follow this advantageous route. Moreover, it is the author's experience that very few patients, although informed of this fact, are willing to wait such a long time for symptom relief.

Until more is known about the disease mechanisms for chronic closed lock and osteoarthritis, we can at best prevent further development of the disease, improve mandibular function, and reduce the pain.

In patients with chronic closed lock, results in a recent randomized clinical study comparing arthroscopic lysis and lavage with discectomy indicate that the first choice of treatment should be the former.³⁵ The results regarding clinical outcome were comparable and both methods had a high success rate. However arthroscopy is less invasive, can be performed under local anesthesia, and is thus also less expensive both for the patient and society. For more information about arthroscopic lysis and lavage, see Chapter 55.

Acute closed lock may be treated in the same manner as a contusion (see TMJ trauma). If the acute closed lock is very recent (within 24 hours) local anesthesia of the joint and gentle manual manipulation may unlock the joint. In the author's experience, this method does not work if the lock has existed more than 2 days, and prolonged manipulation can instead cause more trauma to the joint.

Discectomy

Discectomy has been described previously (see under Reciprocal clicking).

Outcome

Discectomy without replacement has shown good results in several well designed long-term follow-up studies.^{13,22–24,35} It is therefore the method of choice if arthroscopic lysis and lavage has failed.

Complications

The complications have been listed previously under Reciprocal clicking (disc repositioning).

Modified condylotomy

The method has been described under Reciprocal clicking. The same hypothesis is suggested, i.e. that a decreased load on the disc will facilitate adaptation and repair.

Outcome studies

Follow-up studies have been performed showing good outcome.³⁶ The limitations of these studies are high levels of drop-out of patients. The method has yet to be validated in a randomized study comparing it with discectomy.

Complications

The complications are those described under Reciprocal clicking (modified condylotomy).

Osteoarthritis (degenerative joint disease)

As previously mentioned, osteoarthritis frequently runs in conjunction with chronic closed lock and shows mainly the same symptoms except that crepitation is also frequently present.

Outcome studies

There are no specific assessment studies regarding TMJ osteoarthritis. As osteoarthritis and chronic closed lock frequently occur together the studies done for chronic closed lock may also be applicable to osteoarthritis. Thus arthroscopy is the first treatment of choice. Discectomy may be used if arthroscopy fails or if an interfering osteophyte or remodeling is seen on the computed tomography (CT) scan (see Fig. 56.10).

In patients where the TMJ osteoarthritis is part of a generalized osteoarthritis it seems that the success rate is lower.³⁷ In a small number of patients with osteoarthritis the degenerative process seems to induce pronounced adhesions with a high recurrence rate. In these patients an arthroplasty may be indicated.

Complications

The complications are essentially the same as for surgical treatment of reciprocal clicking and chronic closed lock.

Chronic polyarthritis with TMJ involvement

Chronic polyarthritis may involve the TMJ. The most common form is rheumatoid arthritis (RA) and juvenile rheumatoid arthritis (JRA), followed by psoriatic arthritis and ankylosing spondylitis. The prevalence of RA is about 2% in the western world. Women are twice as often affected as men. Reported incidence for TMJ involvement varies from 2–86%, reflecting the fact that definite clinical and radiographic criteria for RA of the TMJ are missing. For psoriatic arthritis and ankylosing spondylitis, there are no reliable figures regarding TMJ involvement. Arthroscopic studies have shown an increased frequency of adhesions and more pronounced synovitis in patients with RA of the TMJ compared to patients with chronic closed lock of the TMJ. Synovial biopsies from TMJs with RA involvement also show more pronounced inflammation.³⁸ The cytokine pattern also seems different from that of osteoarthritis.³⁹

Clinical diagnosis

Chronic polyarthritis usually first appears in joints other than the TMJ and therefore the diagnosis has already been established when the patient comes to the dentist or the oral and maxillofacial surgeon.

However, occasionally the first joint to evince symptoms may be the TMJ.

Acute RA usually demonstrates a swelling over the TMJ and the serology markers are usually raised considerably. In these cases several milliliters of synovial fluid can be aspirated from the joint. Arthroscopy shows typical hyperplasia and hyperemia of the synovium.³⁸ In a small group of patients

with rheumatic disease a frontal open bite and mandibular retrusion will develop (Fig. 56.11). In chronic RA the clinical features may be the same as for chronic closed lock and osteoarthritis, i.e. reduced mandibular movements, joint pain, and crepitation.

Surgical treatment

Surgical treatment comprises intra-articular injection, arthroscopic surgery, discectomy, arthroplasty, and orthognathic surgery. It is the author's experience that the vast majority of patients with chronic polyarthritis and TMJ involvement will benefit from arthroscopic lysis and lavage with or without a ste-

Fig. 56.11 Patients with chronic polyarthritis and TMJ involvement. (a) Patient with ankylosis following TMJ polyarthritis. (b) Another patient with a frontal open bite. (c) Micrognathia of the mandible in another patient.

roid injection. However, in a small group, open bite, mandibular retrusion, and TMJ ankylosis may complicate surgical treatment.

Arthroscopic treatment is described in Chapter 55.

Discectomy

In TMJs affected by chronic polyarthritis the disc is frequently displaced and deformed. The treatment may therefore be similar to that of TMJ osteoarthritis and chronic closed lock. If arthroscopic lysis and lavage fails, discectomy may be performed. However, in TMJs with chronic polyarthritis the chronic inflammation is more pronounced and a selective synovectomy may therefore also be done.

Outcome studies

Very few outcome studies have been performed. Bjornland performed discectomy and synovectomy in 15 patients (25 joints) and followed them in the long term.⁴⁰ Seventy-three percent of the patients improved regarding pain and opening capacity. This study is promising and indicates that discectomy with a selective synovectomy may be the method of choice when arthroscopic lysis and lavage has failed.

Complications

The complications are similar to those described previously for discectomy and disc repositioning surgery.

Arthroplasty

As previously mentioned there is a small group of patients with chronic polyarthritis that develop ankylosis or open bite/mandibular retrusion. Arthroplasty is described in Chapter 55.

Ankylosis induced by chronic polyarthritis is a complicated condition and is more difficult to treat than ankylosis caused by trauma. The recurrence rate is higher because the disease process is difficult to control. Moreover the anesthetic risk is sometimes higher, especially when the neck is involved. Sometimes the reduced mobility in the neck can limit the access to the operation field.

For ankylosis, several methods have been suggested, such as gap osteotomy, chondrochondral graft, auricular graft, dermis, alloplastic grafts, TMJ prostheses, and distraction osteogenesis. The suggested wide variety of methods indicates that there is still not a satisfactory treatment. More tissue-related research is needed to understand why some patients do not respond to the treatment. All that are involved in TMJ surgery recognize a small group of patients that seem to have recurrence of ankylosis, whatever treatment is given. They show ectopic bone formation in the TMJ and probably represent a genetic variant. The solution to this problem is not yet another prosthesis but to focus more on tissue research.

Sound principles for surgical treatment are that the least invasive method in terms of complexity, trauma, social complication, and cost that benefits the patients should be preferred. At present, both for children and adult patients, the author prefers to use a gap osteotomy and interposition with temporalis muscle. This method may serve as the reference procedure in future randomized clinical trials.

TMJ trauma

In all cases with mandibular trauma, there is also an associated injury of the soft tissues of the joint. The term contusion or traumatic arthritis may be used.

Clinical findings

In unilateral cases there is a lateral open bite on the affected side and the mandible deviates to some extent towards the opposite side (Fig. 56.12). Joint pain is provoked if pressure is applied to the chin. In rare cases the contusion can be bilateral and in these cases a frontal open bite occurs.

Differential diagnoses are fracture of the condylar neck and mandibular luxation. The first is ruled out because the clinical features differ from that of a contusion. In unilateral condylar neck fractures the mandible deviates towards the affected side and the lateral open bite develops on the opposite side. Unilateral mandibular luxation may show the same clinical features as a contusion but there is usually no history of trauma. Radiographic examination is of value in these cases.

Treatment

In most cases with contusion of the TMJ symptomatic treatment is sufficient. The patient is put on a soft diet and is given anti-inflammatory medication and analgesics. Usually, the symptoms subside within 10 days and the occlusion returns to normal. In a few patients an acute closed lock may develop because a lacera-

Fig. 56.12 Traumatic synovitis of the right TMJ after a blow to the chin resulting in a lateral open bite on the right side.

tion in the posterior disc attachment occurs resulting in an anterior displacement of the disc. In these cases, arthroscopy or TMJ surgery may be indicated.

Long-term consequences

It has been shown that patients with TMJ reciprocal clicking and chronic closed lock have a much higher reported occurrence of previous trauma to the jaw compared to controls.⁴¹ Clicking and locking symptoms may develop many months after the trauma episode which is important to remember when insurance matters are dealt with.

TMJ abnormalities

TMJ abnormalities are infrequent compared to functional disorders. However, the treatment can often be complicated and demanding, particularly in children. TMJ abnormalities may be either congenital or acquired.

Congenital abnormalities

The most common congenital abnormalities are hemifacial microsomia (incidence 1 in about 5600 living births) and Treacher Collins syndrome (incidence 1 in about 10000 living births). These conditions are best treated in specialist centers where a sufficient number of patients enable development of experience and there are more possibilities for evaluation. Some of the surgical treatment methods are described in Chapters 49a and 49b.

Acquired abnormalities

Condylar hyperplasia

Excessive growth of the mandible may affect only the condyle, the condyle and the ramus, or the whole mandible. The condition is usually unilateral. Several thorough reviews have been published but it is still unclear how the condition develops and progresses. It is more common in females than in males and it usually becomes detectable in the early teens. In these patients the excessive growth usually ceases when normal growth has ended. However, there are also cases where a recurrence of growth takes place after cessation of normal growth. In these patients the growing condyle is not only hyperplastic but also shows asymmetric growth; it has been questioned whether these cases are true condylar hyperplasias or may instead be development of an osteochondroma.⁴²

Classification

The condition may be either of a vertical or rotational type. In patients with the vertical type the growth has a mainly vertical direction leading to a long ramus of

the mandible and a lateral open bite on the affected side depending on the age at which it occurs. If the patient is young, the maxilla can grow down to match any open bite, instead producing an occlusal cant. Usually there is no contralateral crossbite and only a slight deviation of the chin point or dental midline.

In patients with a rotational type, besides a long ramus, the chin point deviates to the contralateral side. Intraorally, there is a crossbite on the contralateral side. The dental midline also deviates to the normal side.

Diagnosis

It is most important to determine whether the condition is in a residual (inactive) stage or not. Repeated occlusal assessments may be one method of detecting growth. However, compensatory growth of the maxilla may occur concealing the actual growth. Radiographic examination may reveal a size difference of the condyle between the right and left sides which may indicate condylar hyperplasia. However, it has to be remembered that the condyle normally shows variation in size and form. Especially when only a panoramic radiograph is taken the distortion can be considerable depending on the angle of the long axis of the condyle. A CT scan is therefore more reliable. Bone scintigraphy, especially when combined with CT, is a reliable method for detection of metabolic activity in the condyle and may also show if the activity is found in other parts of the mandible or only related to the condyle. The uptake in the condyle must be pronounced and clearly differ from that of the contralateral condyle. It must also be remembered that other conditions, such as osteomyelitis and arthritis, may also show a high uptake.

Surgical treatment

In the growing child there are two options. If the child has a mild anomaly and is close to when cessation of normal growth is predicted, observation may be an option. However, if the anomaly is considerable and there is a long time until cessation of growth, a resection of the abnormal growth center in the superior part of the condyle is recommended (Fig. 56.13). After normal growth has ceased and if no further growth is seen in the condyle, orthognathic surgery is undertaken to correct the mandibular asymmetry. In the adult patient, the growing condyle has to be resected and a simultaneous reconstruction performed.

Another important thing to understand is that mandibular hyperplasia is a disease of the mandible. This means that the disc and the temporal component are not affected. Another thing that can be advantageous is that the condylar neck is frequently thicker than normal and may therefore be large enough to act as a new condyle. This observation has formed the basis for an elegant and simple solution to the reconstruction task (Fig. 56.14). The condyle is first resected via a preauricular approach. The lateral part of the ramus is then exposed via a submandibular approach

Fig. 56.13 A 14-year-old girl with an actively growing condylar hyperplasia. (a) Clinical picture showing deviation of the chin to the opposite side. (b) Occlusal view showing crossbite on the opposite side. (c) SPEC-SCAN showing increased uptake in the right TMJ.

and a vertical osteotomy performed in the posterior part. This posterior segment may be regarded as a bone-muscle flap as it has muscle attached to it medially. The superior part is smoothened and pushed up against the disc. Fixation to the remaining part of the ramus is done with miniplates.⁴²

Another method recently described for hemifacial microsomia is to use distraction osteogenesis.⁴³ The condyle is resected and an L-osteotomy is then performed in the posterior part of the ramus. The segment is then gradually advanced superiorly to form the new condyle. The method avoids the problem with donor site morbidity but it is complicated and expensive.

The condyle can also be reconstructed using a costochondral graft; this was often used in the past. It involves a certain risk of donor site morbidity and asymmetric excessive growth of the graft, which in turn can result in a mandibular asymmetry.

In cases with the rotational form, simultaneous orthognathic surgery is frequently required as well as pre- and postoperative orthodontic treatment.

Patient numbers are often very small which makes reliable evaluation difficult. A solution for the future may be to perform multicenter studies. Considering the publications up to the present, it seems that the method using the bone-muscle flap is to be recommended.

Complications may include a temporary palsy of the temporal and marginal mandibular branches of the facial nerve or the inferior alveolar nerve. If simultaneous orthognathic surgery is performed there is also a small risk of postoperative infection.

Ankylosis

Ankylosis, by definition, means that the joint is fused with bone. However, the term has often been broadened to also comprise fibro-osseous or fibrous fusion of the joint. The condition may occur after trauma (most frequent), infection, chronic polyarthritis, or as a result of radiation therapy. It occurs both in adults and children, more often in the latter.

Diagnosis

The diagnosis is rarely difficult. There is no translation of the disc-condyle complex and only a limited rotation. In unilateral cases, this is reflected by a marked deviation to the affected side in maximum opening and protrusion. The laterotrusion to the unaffected side is usually zero. In bilateral cases, the interincisal opening usually varies between 5 and 15 mm and there is no protrusion or laterotrusion.

CT examination reveals a bony mass in the joint area. In cases with fibrous ankylosis there may be an arthrotic appearance of the joint surfaces. CT is also valuable to display the medial extent of the bony mass.

Surgical treatment

The surgical protocol involves resection of the bone mass, creating a gap of about 10 mm both laterally and medially. If interincisal opening is still limited after this procedure, an osteotomy (or ostectomy) of the coronoid process may be performed as well. This will usually lead to an interincisal opening of about 35 mm or more.

Fig. 56.14 Patient with a rotational type of condylar hyperplasia. (a) Clinical picture. (b) Intraoral view showing open bite on the right side. (c) Radiograph showing enlarged condyle, collum, and ramus. (d) Simplified drawing showing the surgical technique used to reconstruct the TMJ. (e) Occlusion 5 years postoperatively. (f) Radiograph 5 years postoperatively.

The TMJ may then be reconstructed in several ways. In the past costochondral graft was the method of choice. However, excessive growth of the graft can result in mandibular asymmetry. This occurs most frequently in the child but may also occur in adults. The costochondral graft may be used with or without an interpositional material. Several such materials have been used in the past, autogeneous such as auricular cartilage, dermis, temporalis fascia, and temporalis muscle, or alloplastic, such as Silastic, Proplast, and several models of TMJ metal prostheses. Another recently suggested method is to use distraction osteogenesis (see under Condylar hyperplasia).

Reviewing the literature indicates that TMJ prostheses and costochondral grafts should be used with caution. There are no reliable data showing how long a prosthesis is going to function before it has to be replaced. Since most of the TMJ patients are relatively young this may lead to repeated replacements with a considerable risk of nerve damage. Costochondral

grafts have the disadvantages of donor site morbidity and the possibility of excessive asymmetric growth. Moreover, interposition of alloplastic materials (Proplast and Silastic) has led to problems of fragmentation, giant cell formation, and failure.

As previously mentioned there is in general a lack of well-designed outcome studies comparing different methods. Moreover, the numbers are small. As mentioned before we therefore have to rely solely on clinical experience which is not ideal. Until more research has been carried out, it seems most recommendable to rely on gap osteotomy with interposition of a temporalis muscle flap as the standard procedure.⁴⁴ The thick muscle flap may fill the gap and prevent an open bite. A new condyle may also be created surgically by advancing the posterior segment of the ramus after performing a vertical osteotomy (Fig. 56.15). An alternative method may be to use distraction osteogenesis. However, this method is more complicated and expensive.

Fig. 56.15 Patient with ankylosis of the right TMJ after trauma. (a) Preoperative panoramic radiograph. (b) Preoperative three-dimensional CT (notice the elongated coronoid process on the right side). (c) The right TMJ after resection of the ankylotic bone. The temporalis muscle/fascia flap is outlined. (d) The flap rotated down and sutured into the joint. The condylar stump is advanced superiorly below the interposed muscle flap after a vertical ramus osteotomy.

Fig. 56.15 (cont'd) (e) Postoperative panoramic radiograph. (f) Maximum opening of 41 mm at 3-year follow-up examination (compares with preoperative opening of 10 mm). (g) Occlusion at 3-year follow-up examination.

The most disturbing complication after TMJ ankylosis operations is reankylosis. The reported figures vary from 0–37%. Complications with costochondral grafts are overgrowth of the graft, malocclusion, persistent pain, and donor site morbidity. Gap osteotomy may have the least complications. Temporalis muscle flap may create muscle symptoms at the donor site. In patients with TMJ prostheses, joint failure, Frey's syndrome, and persistent pain seem to be most common.

TMJ tumors

Tumors of the TMJ are extremely rare. In a review of 3200 tumors of the head and neck only seven (0.2%) were located in the TMJ. The majority of these tumors are benign.

Benign tumors

Benign tumors include osteoma, osteochondroma, chondroma, chondroblastoma, fibro-osteoma, sarcomatosis, and pseudotumors such as synovial chondromatosis and pigmented villonodular synovitis. In this chapter, the most common of these rare tumors will be described, namely osteochondroma and synovial chondromatosis.

Osteochondroma

Osteochondroma is a cartilage-capped bony outgrowth of the condyle and in the literature it has often been confused with condylar hyperplasia or chondromas.⁴² The outgrowth is most common in the anterior and medial part of the condyle. Other loca-

tions in the mandible have also been found, such as the coronoid process. As the outgrowth seems to follow the tendons of the lateral pterygoid and temporal muscles the suggested explanation has been that a continuous strain on these tendons results in an overgrowth of cells with chondrogenic potential.

Osteochondroma of the TMJ seems to occur more often in females, with a later onset than in the long bones where the onset usually takes place within the first two decades.

Diagnosis

The tumor is usually very slow growing, with a gradual deviation of the chin to the opposite side and a lateral open bite on the same side. Usually the condition is symptom-free but slight pain may be present in a few cases. Thus, the indication for surgery is mainly if the patient is disturbed by malocclusion or the esthetics. Two of the author's patients had had their osteochondromas for several years, having no symptoms. They also had a malocclusion and deviation of the chin but declined surgery as they had no symptoms. They were followed for a decade until they passed away showing no additional growth or symptoms. Thus the indication for surgery may not be clear-cut in these cases but has instead to be determined on an individual basis.

Surgical treatment

The surgical protocol is similar to that for condylar hyperplasia. In most cases the TMJ disc is not affected. If the disc is perforated and degenerated it has to be removed and replaced by a temporalis muscle flap. The condyle has to be resected but the condylar neck may be used as a "neocondyle" after performing a vertical ramus osteotomy with superior advancement

of the posterior segment as previously described for condylar hyperplasia (Fig. 56.16). In a few cases simultaneous orthognathic surgery may also be needed.

Outcome studies have been small and no comparative studies have been performed. The limited experience that exists until now seems to favor the above described surgical treatment.

The complications are the same as described for surgical treatment of condylar hyperplasia.

Synovial chondromatosis

The disease is not a true neoplasm but is better regarded as a metaplastic activity within the synovial membrane. For unknown reasons, the synovial membrane starts to produce small cartilage particles which are then released into the joint cavity.⁴⁵ It seems that some of them can grow considerably and the author has found free bodies more than 1 cm in size. The

number of free bodies may be as many as 100. Interestingly, the disease seems to be limited to the upper compartment. If free bodies are found in the lower compartment there is always a disc perforation present allowing the particles to slip into the lower compartment.

Some reports have appeared in the literature indicating that synovial chondromatosis has a malignant potential, but this is not generally believed. On the contrary the disorder seems benign and is easily treated. Nevertheless, until we have more data a long follow-up period is needed in these patients.

Diagnosis

Clinical signs and symptoms may be rather varied (Fig. 56.17a–c). Recurrent swelling lateral to the TMJ without any signs of infection, degenerative or rheumatic disease may indicate synovial chondromatosis. Pain may be present but not always.

Fig. 56.16 Patient with osteochondroma of the right TMJ. (a) Clinical picture. (b) Occlusion is prenormal and deviates to the opposite side. (c) Panoramic radiograph showing a large osteochondroma of the right TMJ. (d) Postoperative panoramic radiograph showing the surgical procedure (resection of the tumor, advancement of the condylar stump, sagittal split on the opposite side). (e) Postoperative occlusion.

A CT scan usually displays free bodies in the TMJ as at least some of the fragments are calcified. However, there are also exceptional cases where no calcified bodies are seen and where the free bodies are also difficult to depict on MRI, because of the high water content of the cartilage fragments.⁴⁶

Arthroscopy is very accurate in diagnosing synovial chondromatosis. Symptomatic relief can also be obtained by flushing out the majority of the smaller fragments and the excess synovial fluid that creates

the swelling. However, the bigger fragments cannot be removed arthroscopically and open surgery is therefore often necessary.

Surgical treatment

Surgical treatment (Fig. 56.17d, e) involves exposure of the joint via a preauricular approach. The free fragments are removed, paying attention to the anterior and medial recess where a number of fragments may hide. Synovial areas with evident chronic inflamma-

Fig. 56.17 Synovial chondromatosis of the right TMJ. (a) Clinical picture. Notice the swelling over the right TMJ. (b) Preoperative MRI showing an expanded TMJ capsule and fluid. (c) CT showing some calcified free fragments in the TMJ. (d) Surgical exposure of the right TMJ. Fragments emerge from the joint on incision of the lateral capsule. (e) The fragments found in the joint. Some of them are almost 10mm in diameter.

tion may be resected, using diathermy or a laser. If an associated perforated disc is found the disc may be excised without any replacement.

Similar to other rare TMJ conditions, there are few reports in the literature. A recent study of nine patients with a clinical and MRI follow-up between 1 and 6 years indicated that the above described conservative approach for surgical treatment may be best,⁴⁵ at least until multicenter comparative follow-up studies provide more thorough information.

Recurrence may be a complication as may malignant transformation. The risk seems to be extremely low. Other complications may be similar to those for TMJ disc derangement.

Malignant tumors

Malignant tumors in the TMJ are extremely rare. The author has only diagnosed two malignant tumors, one in the TMJ and the other in an extra-articular location. The tumors may be either primary or metastatic. Metastatic tumors are usually carcinomas originating from a wide variety of primary tumors. Primary TMJ tumors are sarcomas of chondral, fibrous, synovial, or bony origin. It is necessary to try to describe the criteria that differentiate a malignant tumor from a benign one.

Diagnosis

A malignant tumor may have clinical signs and symptoms that show great resemblance to that of TMJ arthritis or chronic closed lock, e.g. swelling, impaired mobility of the TMJ, and pain. The author can relate a case where the patient was initially treated for a chronic closed lock of the TMJ for a period of several months before referral. The clinical signs and symptoms indicated no malignant tumor. The panoramic radiograph did not indicate any arthritis or tumor and it was not until a CT scan was performed that the diagnosis became evident (Fig. 56.18). In cases with signs of TMJ arthritis and chronic closed lock, a CT (or MRI) scan is therefore strongly recommended.

Surgical treatment

Surgical treatment usually includes a craniotomy with a wide excision of the tumor, radiation therapy (if the tumor is not radioresistant), and chemotherapy. Reconstruction may include temporalis muscle flap and distraction osteogenesis or orthognathic surgery.

Complications may include permanent palsy of the facial nerve, Frey's syndrome, and recurrence of the tumor.

Fig. 56.18 Patient with an osteogenic sarcoma of the TMJ. (a) Initial panoramic radiograph giving no indication of a destructive process in the TMJ. (b) CT showing the typical features of a malignant process in the TMJ.

TMJ infections

In the past infections of the TMJ were not uncommon and even nowadays such infections exist in countries where access to health care is limited. Infections may reach the TMJ from a penetrating wound, adjacent tissues, or by hematogenous spread.

Penetrating wounds may include TMJ surgery or condylar fractures with laceration of the external auditory meatus. Ear infections may spread directly to the TMJ because of the very thin barrier between the ear and the TMJ. Infection may spread from the mouth and the teeth through the pterygoid and infratemporal spaces. Recently, much interest has been focused on the possibility of hematogeneous spread of some microorganisms known for their ability to induce reactive arthritis. One such microorganism of interest is *Chlamydia trachomatis*.⁴⁷

Clinical diagnosis

The clinical signs and symptoms may vary. In some patients the swelling is evident, yet in others the swelling is discrete and may be difficult to distinguish from a traumatic synovitis or chronic polyarthritis. A thorough history is important: Is there a generalized joint disease? Any trauma? Bruxism? Teeth infection? Ear infection? Are there any systemic signs of infection such as fever and leucocytosis?

Usually there are no hard tissue changes in the early phase of the infection. However an increased joint space may be seen as well as changes in the occlusion (lateral open bite on the same side). MRI is more accurate and may also demonstrate abscesses in the adjacent structures. Fig. 56.19 shows a patient with a suppurative TMJ infection which originated from a postoperative infection after removal of the lower left third molar.

Surgical treatment

Incision and debridement of the abscess is important. Before incision, aspiration is performed for culture and determination of suitable antibiotics. The joint may be irrigated arthroscopically in some cases. If the joint tissues have been damaged it may be necessary to perform an arthrotomy and remove necrotic tissue and adhesions.

Extra-articular connective tissue diseases

Hyperplasia of the coronoid process

Mandibular hypomobility is most often related to TMJ pathology or has a muscular origin. However, there are also other conditions that can impair mandibular mobility. Hyperplasia of the coronoid process

is such a condition, and is sometimes overlooked. In the literature it has been reported occasionally⁴⁸ since the end of the 19th century when Jacob described the first case.

Diagnosis

The clinical complaint is usually slowly progressing restricted mandibular opening. The patient usually points to the anterior part of the superior insertion of the masseter muscle and not to the TMJ. There is no history of clicking or ear pain. In most cases translation can be palpated in the TMJ when performing protrusion and laterotrusion. Sometimes crepitation may be experienced by the patient in the area of the coronoid process.

CT provides valuable information. The picture may vary from patient to patient. In some patients the coronoid process is elongated and inclined with a clear impingement against the posterior surface of the zygomatic bone or the zygomatic arch. In some patients an osteochondroma has formed and in yet other patients the elongated process seem to have created a "pseudo joint" with the temporal bone. In some patients the coronoid process is very broad, causing impingement on adjacent soft tissues.

If the condition develops in young individuals it seems to be combined with a "square mandible", class II occlusion, and a deep bite (Fig. 56.20).

Differential diagnosis may include buccal eruption of the third molars in the maxilla and hyperplasia of the maxillary tuberosities both of which may narrow the space for forward translation of the coronoid process upon opening. The author has seen two such cases where the coronoid processes were clearly elongated in combination with buccal eruption of maxillary third molars. After removal of the third molars bilaterally the maximum opening increased from 20mm to more than 40mm within a week and no impingement of the coronoid processes was noted despite the suggestion of it by the radiologist (Fig. 56.21).

Surgical treatment

If a clear impingement is diagnosed, the coronoid processes can be removed through an intraoral approach. The coronoid process is exposed in the same manner as for a vertical osteotomy. The process is cut at the base with a bur or a saw and removed.

No long-term, well designed outcome studies have been published as yet. The occasional case reports all seem to report a good outcome.^{48,49} Very few complications have been reported. Infection may be one, which is easily managed.

Fibrosis of temporalis tendon

This condition may show the same clinical features as hyperplasia of the coronoid process.

Fig. 56.19 Odontogenic infection with spread to the TMJ. (a) Clinical picture at admission. (b) Panoramic radiograph showing an empty alveolar socket after extraction of left lower wisdom tooth. (c) Incision and drainage of the abscess. (d) Tomogram 1 year after treatment showing severe destruction of the TMJ but remarkably there were no symptoms.

Diagnosis

In these patients the coronoid process is usually not elongated or hyperplastic but may be broad and short. The tendon is usually painful when palpated intraorally and feels tight.

Surgical treatment

The surgical treatment mainly follows the same protocol as for condylar hyperplasia. However, as there is no impingement, an osteotomy of the coronoid process may be sufficient in these cases. In some of

Fig. 56.20 A 16-year-old boy with elongated coronoid processes and difficulties in mouth opening. (a) Clinical picture showing a "square mandible", slight postnormality and a deep bite. (b) Preoperative interincisal opening of 16 mm. (c) Elongated right coronoid process. (d) Elongated left coronoid process. (e) Interincisal opening of more than 30 mm after bilateral osteotomy of the coronoid processes.

Fig. 56.21 Patient with chronic pericoronitis of impacted upper wisdom teeth. The teeth were partly erupted and caused impingement on the surrounding soft tissue. Maximum opening before extraction of the teeth was 15 mm. (a) Preoperative panoramic radiograph. (b) Maximum opening 2 weeks after extraction.

these patients the masseter muscle and its attachment also show fibrosis and sometimes even thick bands. These can often be released through the same intra-oral incision.

The occasional reports published indicate that the above protocol may have a good outcome in some patients. However, the recurrence rate seems high for these patients. The complications are the same as described for condylar hyperplasia.

Eagle's syndrome

The condition is related to an elongated styloid process. Normally the process is about 2.5 cm long and a process longer than 3 cm is regarded anomalous. Styloid process anomaly was first mentioned by Marchetti in 1652. Eagle described two forms based on the clinical symptoms.⁵⁰ The first category was related to the elongated styloid process and is characterized by pharyngeal pain located to the tonsillar fossa. The second category corresponded to the stylo-carotid syndrome and is related to persistent pain in the carotid area. The incidence varies in the literature,

reflecting the difficulty in finding precise diagnostic criteria.

Diagnosis

A problem is that many patients show calcification of the stylomandibular ligament on radiographs but have no symptoms. Therefore, only patients presenting with a clearly elongated and deviated styloid process may be relevant. In these patients the tip of the process may also be palpated in the fossa tonsillaris. The clinical symptoms may be a foreign body sensation in the fossa tonsillaris and sometimes pain when swallowing, chewing, or rotating the head. A diagnostic local anesthetic block of the fossa tonsillaris may be useful in cases of uncertainty.

Surgical treatment

Access to the elongated styloid process is achieved through a transpharyngeal approach.⁵¹ An incision is made in the tonsillar area over the palpated styloid tip. The tip is then exposed and resected (Fig. 56.22).

Fig. 56.22 Patient with elongated styloid process on the left side causing pain in the tonsillar area. (a) Panoramic radiograph showing the elongated styloid process on the left side. (b) Excised part of the styloid process.

There is usually no need for tonsillectomy. An extra-oral approach has also been described, utilizing a retromandibular approach.

There are only case reports published. These indicate a good outcome with the above-described technique. Complications may include intraoperative bleeding and postoperative infection.

Chapter 57

Temporomandibular Joint Reconstruction

Anders Westermarck

When severe destruction or ankylosis of the temporomandibular joint occurs, joint replacement may be necessary. Although there are a number of autogenous sites that have been used over the years, the costochondral graft is the one that is most frequently employed. Alloplastic joints are now available and there are a handful of different types that are manufactured and commercially available. Most are similar to orthotopic alloplastic joints in that they are often made of titanium with a chrome/cobalt surfaced head and an ultra high molecular weight polyethylene glenoid fossa.

This chapter will describe the indications for joint replacement and the materials and techniques available.

Future perspectives, 1246

Temporomandibular joint (TMJ) reconstruction is not a treatment for general TMJ problems. It should be considered end-stage surgery, and is therefore a rather exclusive treatment modality. Indications for TMJ reconstruction include:

- severe degenerative joint disease;
- bony ankylosis;
- irreparable condylar fracture;
- neoplasia requiring resection of joint components;
- congenital malformation;
- previously failed reconstruction.

The term TMJ reconstruction should be reserved for the situations when both the condyle and the fossa are reconstructed. Otherwise, one should use terms such as condylar replacement and fossa reconstruc-

tion, respectively. In various reconstructive procedures of the TMJ one can choose between autogenous material and alloplastic devices.

Autogenous reconstruction

As with most things in medicine and surgery, there is little that is truly new. In 1927 Wassmund described the use of free metatarsal grafts for condylar replacement.¹ Other donor tissues that have been used for condylar replacement include clavicle,² iliac crest,³ and vascularized fibula.⁴ Of all the autogenous donor sites, however, ribs have been used more than anything else. Rib grafts can be used either as free⁵⁻⁸ or vascularized⁹ costochondral grafts. The costochondral graft consists of both bone and hyaline cartilage.

The popularity of costochondral grafts for condylar replacement is based on several factors. Ribs are relatively easy to harvest. The size of the graft usually fits the native TMJ dimensions, and it is rather easy to adapt the rib and its cartilage to the local conditions. In patients who are not skeletally mature, the costochondral graft may have some persisting growth potential.

The growth potential is, however, a potential disadvantage of the costochondral graft. The graft may grow too much, too little, or not at all. Children who have had condylar replacement with rib grafts may have to undergo further surgical procedures to correct the jaw position later on.

The downside of costochondral grafts also includes things they have in common with other autogenous grafts, such as ankylosis/reankylosis (Fig. 57.1), resorption (Fig. 57.2), and donor site morbidity. While costochondral grafts for condylar replacement do relatively well in many instances, they are not overly reliable in the treatment of TMJ ankylosis. Saeed and Kent found that a preoperative diagnosis of ankylosis was associated with an *“increased complication and further surgery rate, suggesting caution in this group of patients”*.⁷

Fig. 57.1 CT scan with a frontal view of a costochondral graft attached with screws to the lateral aspect of the mandibular angle. The radiolucent area under the skull base represents the cartilaginous part of the costochondral graft. The contour of the graft can also be identified, although it is surrounded by a robust heterotopic bone formation.

Fig. 57.2 Along with resection of the mandibular ramus in an 8-year-old boy, the ramus and condyle were reconstructed with a costochondral graft. The graft has undergone degeneration that has resulted in loss of continuity mid-way. Note that the cartilage of the graft does not appear in this three-dimensional image.

Costochondral grafts for condylar replacement

Usually, the costochondral graft is used as a free, non-vascularized graft. The recipient site should be prepared first, therefore, so that the time from rib harvest to installation can be kept as short as possible.

Kaban *et al.* represent a group of surgeons who have great faith in costochondral grafts for condylar replacement, including the treatment of ankylosis.⁵

Fig. 57.3 Three-dimensional image of a CT scan obtained from a patient with severe TMJ ankylosis. Note the massive fusion between the mandible and the zygomatic complex. The heterotopic bone formation eliminates the contours of condyle, sigmoid notch, and coronoid process. In this case the coronoid process was fused with the temporal bone.

Their protocol for management of TMJ ankylosis has become more or less the standard approach for costochondral replacement of the condyle in general, not only in ankylosis. Their protocol consists of seven stages: (1) aggressive resection; (2) ipsilateral coronoidectomy; (3) contralateral coronoidectomy when necessary; (4) lining of the TMJ with temporalis fascia or cartilage; (5) reconstruction of the ramus with a costochondral graft; (6) rigid fixation; and (7) early mobilization and aggressive physiotherapy.

The coronoid process often becomes enlarged in association with TMJ ankylosis. This enlargement may interfere with the mobilization of the mandible. Sometimes, the coronoid process may even be fused with the temporal squama or the zygomatic arch (Fig. 57.3). In cases where the condyle is replaced for other reasons than ankylosis, such as rheumatoid arthritis, the coronoid process may be left untouched.

Surgical access to the TMJ area is limited by the extent of the facial nerve. Therefore, the costochondral replacement of the condyle will require two surgical approaches: one preauricular, and one retromandibular or subangular. Because one must harvest a pedicled temporalis fascia flap to line the fossa, the preauricular incision must reach rather high, with a posterior–superior convexity of the incision line. The temporal fascia flap is based just over the root of the zygomatic arch. It is then swung over the lateral part of the arch, to line the roof of the fossa and, ideally, also the medial wall of the wound cavity (Fig. 57.4). It is often surprising how long the flap must be to achieve all this. If, however, the condyle is replaced in patients with a persisting disc, there is no need for a temporal fascia flap.

The access to the mandibular angle and ramus can follow several routes. Either a submandibular or a retromandibular incision is made.¹⁰ The latter has gained increased popularity in spite of the delicate transparotid route and close encounter with facial nerve branches. The reward of this route is excellent

Fig. 57.4 (a) A 3-year-old boy has developed a unilateral TMJ ankylosis following urosepsis. After release of the ankylosis and preparation of the fossa region, a temporalis fascia flap is designed to line out the fossa. (b) The temporalis fascia flap has been brought around the base of the zygomatic arch, and is sutured medially in the fossa cavity. The cartilaginous part of the costochondral graft is resting on the soft tissue lining created by the temporal fascia flap.

exposure of the posterior part of the ramus. The submandibular incision only interferes with the marginal mandibular branch of the facial nerve, but does not reach as high on the ramus as the retromandibular incision does. For most purposes, however, the submandibular approach is sufficient.

The rib harvest is done through a more or less horizontal incision below the inferior border of the pectoralis muscle. Usually, rib harvest is made from rib number five, six, or seven. Sometimes it is suggested that a rib from the contralateral side is easier to fit than one from the ipsilateral side. Thereby, in bilateral cases, one should harvest one rib from each side. On the other hand, it may be preferable to only harvest from one side, to reduce the risk of bilateral pneumothorax. After dissection through the skin and subcutaneous tissues the rib periosteum is cut through parallel to the rib. The subperiosteal dissection is carefully carried out around the rib, 4–5 cm in length. About 1 cm of the hyaline cartilage is enough to serve as the condylar head. It is important to maintain a strip of periosteum/perichondrium around the rib/cartilage junction (Fig. 57.5). This will create a support for the cartilage, which otherwise may separate from the rib. The dissection of this periosteal/perichondrium sleeve is much more difficult than the subperiosteal dissection around the bony part of the graft. The rib is preferably cut with a special rib cutter, which is designed to give as much rib as the incision will allow. After the rib has been removed, it is important to examine the tissue bed for any sign of

Fig. 57.5 Subperiosteal dissection is carried out around rib number six in the same patient as in Fig. 57.4. Note that the periosteum/perichondrium around the junction between bone and cartilage is preserved to prevent the cartilage from falling off the bony part.

pleural tear. The wound is filled with saline, and the anesthetist inflates the lungs maximally. A pleural tear will show up as a bubbling in the fluid. If such a tear is present, it should be closed at this time. Postoperatively, a chest radiograph must be obtained to ensure absence of pneumothorax.

The cartilage part of the rib can easily be carved with a regular scalpel blade, and thus be given an optimal fit into the fossa (Fig. 57.6). The costochondral graft will require a certain period of fixation to fuse with the native mandibular bone. This creates a conflict with the need for early mobilization and

Fig. 57.6 After harvest, the cartilage of the costochondral graft has been cut to fit the contour of the reshaped fossa.

aggressive physiotherapy. Ribs are sometimes also rather soft, especially in younger patients, so rigid fixation may be difficult to achieve. Screws alone may not be enough, and in such cases a plate can be used, to serve as a washer. Steel wires can also be used for fixation of the graft (Fig. 57.7). It is sometimes suggested that both the mandibular ramus and the rib graft should be decorticated over the surfaces that meet, in order to increase healing.⁸ Other authors claim that this is not necessary.¹¹ Kaban *et al.* recommend an intermaxillary fixation (IMF) for 3–10 days, “depending on the thickness and rigidity of the costochondral graft”,⁵ while Quinn recommends IMF for 4–6 weeks.¹¹

After release of the maxillomandibular fixation the patient can start on a soft diet and jaw-opening exercises. Active opening and manual finger stretching are advised at this time. During the next few weeks the diet can be more advanced and the exercises increased. Heat, massage, ultrasonography, gum chewing, and manual stretching exercises can be used in order to reach the opening capacity that was achieved during surgery. If this degree of opening

cannot be reached with physical exercises, one might consider tissue stretching under general anesthesia.⁵

Fibula grafts for condylar replacement

Costochondral condylar replacements are usually applied as non-vascularized grafts. Such an option does not exist for fibula grafts. The fibula is composed of very dense, cortical bone, which requires a vascular supply for survival. With the development of microvascular anastomoses, the fibula became one of the most popular grafts for mandibular reconstruction. The majority of such cases concern mandibular body resections in the treatment of tumors or osteoradionecrosis. Sometimes such a resection also includes the mandibular ramus with the condyle. In such an instance the fibula can be angulated to build up both the mandibular body and the ramus (Fig. 57.8). A triangular piece of the fibula must be cut out for this body and ramus design. Care must be taken that this procedure does not injure the vessels that are feeding both ends of the fibula graft. The joint disc usually can be preserved in these cases, so the top of the fibula will be seated on to the disc, and no further soft tissue lining is needed. Sometimes, the lateral pterygoid muscle can be preserved, and can be sutured to the top of the fibula graft, allowing translational movement of the reconstructed condyle to be achieved.

Autogenous reconstruction of the fossa

Tumors, or tumor-like lesions, may destroy the fossa while leaving the condyle and disc undisturbed. In such situations, the fossa alone needs reconstruction. This can be achieved with autogenous, non-vascularized bone. Access to tumors with this localization

Fig. 57.7 (a) A costochondral graft in a 5 year old, attached with screws only. Care must be taken not to insert the screws with too much force. If the rib is very soft, a plate must be added as a washer, such as in Fig. 57.7b. (b) A four-hole miniplate serves as a washer for the osteosynthesis of a costochondral graft to the mandibular angle. (c) Same patient as in Figs 57.4–57.6. In this case the costochondral graft has been placed along the posterior border of the mandibular ramus, and is attached with steel wire osteosynthesis.

Fig. 57.8 (a) A triangular piece of a fibula graft has been cut out to permit contouring of the fibula to match both the body and ramus of the mandible. If a locking plate system is used, one can refrain from stripping the periosteum under the plate. (b) A vascularized fibula graft reconstructing both the body and ramus of the mandible. Note the bony fusion between the fibula and the native mandible.

requires coronal, or hemicoronal flaps, therefore the calvarial bone is readily available as reconstruction material. A piece of bone corresponding to the fossa defect can easily be harvested as a full-thickness graft. The outer and inner tables of the calvarial graft can be separated with thin chisels. One part can then be used to reconstruct the fossa, and the other goes back to the donor site. The graft can be fixed in the fossa with screws, plates, or combinations thereof. One can also use bone from other donor sites (Fig. 57.9).

Prosthetic reconstruction of the TMJ

In his book, *The Rise and Fall of Modern Medicine*, James Le Fanu writes, "John Charnley's hip replacement is, by definition, a successful operation. It is straightforward (the skills can readily be acquired as part of general orthopaedic training), it works, and it lasts. From this one might readily surmise that it is also 'simple', but that would be misleading."¹² This quotation could just as well have been made about prosthetic reconstruction of the TMJ. Not

only do the surgical requirements resemble those of the hip, but unfortunately, the early mistakes do too. With respect to the TMJ, however, the early mistakes were made some 20 years after the same mistakes had been made in total hip reconstruction.

In the early version of the total hip prosthesis, the cup was lined with Teflon. In about 1 year the cup surface had worn out. Wear debris created severe inflammatory reactions. The joint components had to be removed and replaced with new ones. Later, Teflon was replaced with ultra high molecular weight polyethylene (UHMWP) and the results improved dramatically.

In spite of those early bad results in hip replacement, Teflon was also used in a widespread, early type of total TMJ prosthesis, the Vitek-Kent prosthesis.¹³ Just as with the early hip prostheses, the early results were very good. Soon enough, however, problems arose with severe foreign body reactions due to wear debris. The results were just as disappointing as after early Teflon hip reconstructions. Roughly 26000 Vitek-Kent prostheses were installed, and a large

Fig. 57.9 (a) CT scan of the middle cranial fossa. A chondroblastoma has destroyed the fossa of the temporomandibular joint. During tumor surgery, an iliac crest graft has been fitted into the fossa defect and is attached with 2.0mm titanium screws. (b) Lateral view of the same patient as in (a).

number of them had to be replaced later on. In fact, the American Association of Oral and Maxillofacial Surgeons, AAOMS, published guidelines on how to handle failed TMJ prostheses.¹⁴

While the early bad results in orthopedic surgery were soon forgotten and replaced with a faith in the new and better results from improved materials, the same did not occur in the oral and maxillofacial surgical community. For years, the bad results of the early attempts plagued the opinion of prosthetic reconstruction of the TMJ as a reliable treatment modality.¹⁵ Today, however, there are also excellent prosthetic reconstruction devices for the TMJ. For a detailed presentation of the history and development of TMJ prosthetic devices the interested reader is encouraged to read a paper by van Loon *et al.*¹⁶

TMJ prostheses can be divided into two major categories: custom made and stock products. A custom-made prosthesis is one that is made on a model of the patient's skeletal components. Thus, the prosthesis is made to match the patient's individual anatomy. A stock product, on the other hand, is a standard design that comes in various sizes, small, medium, and large. For a stock prosthesis, the bone contour is adjusted to fit the prosthesis. In this chapter, the custom-made TMJ prosthesis is represented by TMJ Concepts, Ventura, California, USA,¹⁷ and the stock prosthesis by Biomet, Biomet Microfixation (previously W. Lorenz Surgical), Jacksonville, Florida, USA.¹⁸

These two prostheses have one thing in common. They both have a fossa made of UHMWP. In the Biomet prosthesis, the fossa is made of UHMWP all through, and the attachment flange comes in three different sizes (Fig. 57.10). In the TMJ Concepts prosthesis the fossa cup is attached to a titanium mesh plate, which is made to fit the patient's individual anatomy (Fig. 57.11). In both types the actual cup of the fossa has only one size. In both types, the fossa

Fig. 57.10 Skull model with a set of Biomet total TMJ prosthesis Biomet microfixation (previously W. Lorenz; Jacksonville, Florida, USA). The mandibular component is made of CoCr with a titanium spray on the surface that faces the bone. There is also a narrow mandibular component. The anterior bulb of the prosthesis here was designed to meet the demands of bony support for screws in patients with previously failed reconstructions, where the posterior part of the ramus might lack good bony support for screw installation. The fossa component is made of UHMWP, and is attached with screws to the lateral aspect of the zygomatic arch.

component is attached to the zygomatic arch with 2.0mm titanium screws.

The mandibular components differ more between the two types. In the Biomet case, the mandibular component is made of cobalt–chromium (CoCr), with a titanium spray on the surface that faces the bone. The mandibular component comes in two different shapes, one standard and one narrow, and they exist in various lengths (Fig. 57.10). In the TMJ Concepts prosthesis, the mandibular component is machined out of titanium. The condylar head is covered with a cup made of CoCr. The mandibular component in the TMJ Concepts prosthesis is first waxed on the patient's model, and then shaped after this model to create the individual fit of the component (Fig. 57.11).

The use of CoCr for the condylar head in both these products is dictated by the wear properties of this material. Both the Biomet and TMJ Concepts prostheses have been subject to experimental testing under conditions vastly exceeding those under normal wear and both are approved by the Federal Drug Administration (FDA) in the USA. Based on the experimental results, one might assume a lifespan of up to 20 years for a total joint prosthesis of such a type. In 2007 Mercuri *et al.* published a study on TMJ reconstruction with up to 14 years of follow-up.¹⁹ They concluded that “outcome data presented show that the patient-fitted total temporomandibular joint reconstruction system continues to be a safe, effective, and reliable long-term management modality for the specific patient population surveyed in this study”. In a recent review Guarda-Nardini *et al.* concluded that “total alloplastic TMJ replacements have shown promising treatment outcomes, and reported improvements are good for both subjective and objective clinical parameters”.²⁰ Basically, the two systems described here, although different in terms of stock vs custom made, are based

Fig. 57.11 An individual three-dimensional model of a patient where a critical size defect has been created in the preparation for a custom-made prosthesis by TMJ Concepts (Ventura, California, USA). The mandibular component is machined out of titanium, and has a condylar head of CoCr pressed on top. The fossa component is, just like in the Biomet device, made of UHMWP, but is attached to a titanium mesh plate formed according to the individual anatomy of the patient. (Reproduced from [26]. Copyright © 2007 Elsevier.)

on modern orthopedic prosthetic principles, developed over decades of hip and knee reconstruction. The collected experience in alloplastic joint reconstruction in the orthopedic community is vast. Installation of knee and hip prostheses in the USA alone runs around half a million per year, while the corresponding figure for alloplastic TMJ reconstruction worldwide, is a couple of hundred per year.

Surgical considerations in prosthetic TMJ reconstruction

The surgical approaches are basically the same as for costochondral condylar replacement. It is important to keep the surgical fields free from oral contamination. Thus, the oral cavity should be excluded from the surgical field with a surgical drape.

The preauricular incision can usually be made somewhat lower than when a costochondral graft is installed, since there is no need to swing down a temporal fascia flap to line the fossa. For the approach to the lateral aspect of the ramus, personal preferences, just as much as anything else, may guide the approach of choice. The dissection should create a subperiosteal tunnel between the two incisions. This tunnel should be wide enough for a little finger to pass through. That is approximately the width required to pass the prosthetic mandibular component through, as well. If this tunnel turns out to be too narrow, it will be much more difficult to widen it once the fossa component has been installed.

In cases with TMJ ankylosis it is important to work meticulously on the mobilization of the mandible. Experience shows that one should be able to pull down the mandibular angle up to 2 cm before one installs the prosthesis. Sometimes such a mobilization will require thorough muscle detachment not only on the lateral, but also on the medial aspect of the ramus. Even after coronoidectomy, the most anterior part of the temporal tendon attachments may persist on the anterior part of the ramus. Once the mandible has

been thoroughly mobilized, the fossa component can be installed. If a stock prosthesis, such as the Biomet, is used, the eminence must be flattened out (Fig. 57.12). The eminence represents the area with the widest range of irregularity in the joint. In the Biomet kit there is a diamond burr which has a contour that matches that of the fossa component. Once the eminence has been flattened out, the sizers (or trials) for the fossa component can be tested. The cup of the fossa is the same in all sizes, only the flange that attaches the fossa to the zygomatic arch differs between the various sizes. Care must be taken to preserve enough bone to attach the screws on the lateral aspect of the arch. Stability is crucial. With the stock fossa one should aim at a tripod support. With a finger one can push the fossa component upwards, and it should stay there without wobbling. Thereafter, the sizer, or “dummy” is removed, and the true prosthetic fossa component is installed. It should be attached with as many screws as the flange holes and available bone will allow (Fig. 57.13).

After the fossa installation, intermaxillary fixation (IMF) must be performed. At this point it is important to realize that the installation of a total TMJ prosthesis requires similar precautions as installation of other joint prostheses. Any contamination of the prosthetic

Fig. 57.12 The eminence has been flattened out with a special diamond burr to create space for the standard fossa component of a Biomet prosthesis. Note that the width of the zygomatic arch is maintained to allow for screw installation.

Fig. 57.13 A Biomet total joint prosthesis has been installed. The signs on the fossa component verify that it is a right-sided, medium-size component. All screw holes have been used. Note that the condylar head is seated in the posterior part of the fossa cup. This is the same patient as in Fig. 57.15. (Reproduced from [26]. Copyright © 2007 Elsevier.)

components may establish a biofilm on the surface of the components. This may result in infection that will require the removal of the implants.²¹ Therefore, when IMF is applied, the wounds must be covered and the oral field must be kept separate from the rest of the surgical fields. Once IMF has been established, the mouth must again be covered with a surgical drape. The instruments from the intraoral procedure must be kept aside, and the surgeon and assistant who performed the IMF must change gown and gloves before they continue the surgical work.

When the mandibular component is installed, care should be taken to seat the condyle in the posterior part of the fossa (Fig. 57.13). This will create the best possible conditions for a good postoperative range of motion. If it is a stock prosthesis, the correct size is tested out with the aid of the sizers. If it is custom made, it is made to fit directly.

Stock components may require some bone surface flattening before they lay passively on the bone surface. This part of the procedure is important, since stability is one of the most critical factors for treatment success. For this reason it is a good idea to study a three-dimensional model of the patient before deciding on what type of prosthesis to use. A stock prosthesis may be problematic in cases with major transverse discrepancies between the fossa region and the ramus. If the fossa is seated too far lateral to the ramus, the mandibular component, with the condyle resting in the fixed cup, will be leaning medially

and reach bony contact only towards the basis of the mandibular angle. Then, the bony work to create a wider bony support for the mandibular component will also reduce the thickness of the bone that will hold the screws. Even if bone harvested from, for example, the coronoid process is installed in the gap superiorly, the stability of the mandibular component may be suboptimal. In such a case a custom-made component is a better choice.

When the first screw is installed in the mandibular component, it is imperative that it is properly centered in the hole. If the first screw hole is made eccentric, the screw will force the mandibular component out of the chosen position and this may disrupt the occlusion. After the first two or three screws are inserted, it may be a good idea to release the IMF and test the occlusion before installing the rest of the screws. Such a procedure should be done with the same aseptic technique as when the IMF was applied before installation of the mandibular component.

It is sometimes advised that the prosthetic components be soaked in antibiotic solution before installation, and also that the wound bed is rinsed with such solution before it is closed. Intraoperative intravenous antibiotic prophylaxis, as well as a postoperative course of oral antibiotics should be maintained. It should also be mentioned that the American Dental Association and American Academy of Orthopedic Surgeons have produced guidelines for antibiotic prophylaxis in patients with joint prostheses. They

Fig. 57.14 (a) Profile radiograph of a 15-year-old patient who has been ankylosed since a very early age. The resulting growth impairment has been so severe that the patient can no longer defend her airway. Shortly after this radiograph was obtained, the patient had a tracheostomy to secure the airway. (b) Resection of bilateral ankylosis followed by installation of TMJ Concepts patient-fitted total TMJ prostheses has resulted in improved pharyngeal airway space. The patient is released from the tracheostomy. The prosthetic devices withstand the posterior pressure put upon them by the suprahyoid muscles. The mandible was advanced as much as the dentition allowed. A genioplasty will follow, to further improve both the airway space and the patient's profile.

recommend that patients who had their prostheses installed up to 2 years previously, should have antibiotic prophylaxis 1 hour before high-risk dental procedures, such as dental extractions, periodontal treatment, etc.²²

One big advantage with prosthetic reconstruction over costochondral or other autogenous reconstruction, is that the patient can, and actually should, exercise right after surgery. Another advantage with prosthetic reconstruction of the TMJ is that the prosthetic devices can withstand the reactive forces that will arise in cases where the mandible is advanced at the time of TMJ reconstruction. Such situations may occur in patients whose joints are severely destroyed by rheumatoid arthritis (RA). One typical feature of a patient with longstanding RA is the bird face, with a variably severe mandibular micrognathia and retrognathia. In such cases an offensive mandibular advancement can be combined with installation of total joint prostheses. A costochondral graft will not give the same postoperative stability. Similar situations may occur in patients who have been ankylosed since an early age. TMJ ankylosis in early childhood will dramatically impair mandibular growth. The resulting micrognathia may become so severe that the patient cannot defend the airway. With the release of the ankylosis and the advancement of the mandible, the pharyngeal airway will increase (Fig 57.14).²³

For the ankylosed TMJ, the risk of recurring ankylosis is always present. It has already been mentioned that costochondral replacement of the condyle in patients with TMJ ankylosis may result in suboptimal outcome, often because of reankylosis. Reankylosis is, however, also a risk after prosthetic reconstruction of the joint. The prosthetic reconstruction requires a rather large gap between the fossa and the ramus. The gap can reach the width of a critical size defect; in this area such a defect is considered to be 2–2.5 cm (see Fig. 57.11). Recently, fat grafting has been intro-

duced as a new treatment modality to further reduce the risk of reankylosis.^{24,25} A free fat graft can be harvested from just under the umbilicus. The fat graft is packed around the joint components to fill empty spaces, before the wounds are closed

Prosthetic replacement of the condyle alone is not recommended.²⁶ On the contrary, it has been demonstrated that fossa erosion frequently occurs if the native condyle is replaced with a metal one without a corresponding fossa component.²⁷ Fig. 57.15 shows a computed tomography (CT) image of a patient who had the condyle replaced with a metal condyle and no fossa prosthesis. The result is dramatic erosion with the condyle seated in a bony cavity just under the middle cranial fossa. The patient suffered from severe pain and restricted jaw movement. Because of that, and, for protection of the brain, a total joint prosthesis had to be installed (Fig. 57.13). As a rule, alloplastic condylar replacement should only be used for temporary purposes (Fig. 57.16).

Congenital malformations may include complete lack of TMJ or deformed joint parts (Fig. 57.17). For TMJ reconstruction of such cases the treatment modality must be chosen after thorough consideration of available alternatives. Often, a custom-made TMJ prosthesis will offer an excellent treatment option. Both the fossa component and the mandibular component can be designed and manufactured to bridge even major bony defects, and to create support for the soft tissue drape. Fig. 57.18 shows a three-dimensional image of the facial skeleton of a patient with Goldenhar syndrome. In the past the patient had been treated with orthognathic surgery procedures in order to mask some of the facial irregularities that were part of the condition. A TMJ Concepts custom-made prosthesis was chosen for the TMJ (re)construction. The joint was designed partly to give the patient joint movement, and partly to give stability to the mandible and the occlusion. Furthermore, the attachment plate for the fossa was designed to build up the missing zygomatic arch, and the mandibular component to give the contour of the mandibular angle.

Fig. 57.15 CT scan of a patient who, 15 months earlier, had a metal condylar replacement installed without corresponding fossa component. The condylar head has eroded into the skull base. The patient suffers from severe pain and a very limited jaw opening capacity. The patient went on to have a total joint reconstruction (Fig. 57.13). (Reproduced from [26]. Copyright © 2007 Elsevier.)

Fig. 57.16 In situations like these, a condylar replacement can be used for temporary purposes. A partial mandibulectomy is carried out because of a rare tumor in the angle of the mandible. The unfamiliar behavior of the tumor calls for an observation period before bony reconstruction is considered.

Fig. 57.17 In a situation like this a stock prosthesis is not a treatment option. A lateral facial cleft and hemifacial microsomia have created a situation where lack of bony tissue calls for bony reconstruction or custom-made prosthetic devices.

Treatment expectations after prosthetic reconstruction of the TMJ

In the very beginning of this chapter it was pointed out that TMJ reconstruction is a treatment option for the joint that is no longer a functioning joint. Sometimes TMJ reconstruction is, actually, TMJ construction, such as in cases with congenital absence of joint components. A long-standing ankylosis means that surrounding muscles and soft tissues have adapted to the immobilized joint, sometimes with severely impaired mobility as a result. In congenital deficiencies there may be total absence of muscles to perform the joint movements. Also, because of loss of function of the lateral pterygoid muscle in most TMJ reconstruction cases, translation is severely impaired. There may be some translational movement because of the lowered rotation point. This inferior hinge axis gives a false translational image to the joint movement. A realistic expectation of opening capacity after TMJ reconstruction is around 35mm. It should be emphasized, however, that the opening capacity to a large extent depends on the patients' compliance with their postoperative physiotherapy. Patients who have suffered from ankylosis must be prepared to maintain a lifelong exercise program to maintain a good opening capacity. There are physical therapy appliances to support these exercises, such as the TheraBite (Cranio Mandibular Rehab Inc, Denver, Colorado, USA) (Fig. 57.19). With respect to pain one must remember that, while most of the joint-related pain will be reduced by the installation of a TMJ prosthesis, muscle pain and myofascial pain may persist. As long as one maintains the correct indications for treatment, one can expect an overall improvement of the patient's quality-of-life scores.¹⁹

Many authors demonstrate a direct correlation between a high number of previous surgical interventions in the TMJ, and a poorer outcome of a final TMJ

Fig. 57.18 A three-dimensional skull model of a patient with Goldenhar syndrome shows lack of the major part of the mandibular ramus, as well as the entire zygomatic arch and the fossa. All missing parts have been reconstructed in a custom-made total joint prosthesis by TMJ Concepts. The fossa component is designed to also create a zygomatic arch. The mandibular component is designed to give soft tissue support in the angular region. Based on the CT scan, the mandibular canal is outlined. The screw holes in the mandibular component can therefore be oriented to avoid interference with the inferior alveolar nerve.

Fig. 57.19 The TheraBite (Cranio Mandibular Rehab Inc, Denver, Colorado, USA) is an example of a useful device for jaw exercise.

reconstruction.²⁰ This probably depends on the extent of scarring following numerous surgical procedures. Dense scarring creates a fibrous wall that impairs healing conditions both after costochondral grafting and after prosthetic reconstruction of the TMJ. It appears that some patients who have had multiple operations would have done better if they had had their TMJs reconstructed at an earlier stage. These observations may serve as a challenge for the future oral and maxillofacial surgeon to identify, at an earlier stage, which patients should have a total joint reconstruction.

Future perspectives

This chapter was written in 2008. There has recently been a rapid development of both experimental and pragmatic tissue engineering.²⁸⁻³⁰ Thus, various facial bone structures designed with computer assistance

have been produced inside the patients' own bodies. Those achievements have used growth factors and stem cells to build bone. The growth factor in these cases has been bone morphogenetic protein 2 (BMP2). The stem cells have been either those present in a muscle that has been transformed into bone, or stem cells derived from bone marrow or body fat. The author of this chapter is confident that the surgical community in the future will develop substances and methods with which we can engineer complex, multipotent autologous structures to become spare parts identical to those they replace. The rate of the development leading to such ideal TMJ reconstructions remains to be seen.
